Introduction

Thyroid cancer is the most common endocrine malignancy. Papillary thyroid carcinoma (PTC), a differentiated type of thyroid cancer, is the most common histological subtype accounting for approximately 70% of thyroid cancer cases (Wartofsky, 2010). Often, surgery is the most successful treatment for PTC patients and is normally
associated with a good prognosis. However, approximately 20–25% of patients develop distant metastases (most in lung and bone) of PTC and have a worse prognosis, since advanced PTC often does not respond to conventional radioactive iodine therapy (radioactive iodine refractory thyroid cancer).

Lung cancer (both small-cell and non-small-cell lung cancer – NSCLC) is the most common cancer (80–85% of all cases) and is the most common cause of death from cancer worldwide. In addition, approximately 50–70% of patients with lung adenocarcinoma, one type of NSCLC, after surgery relapse within one year and their cancer cells acquire a chemoresistant phenotype (Ramalingam and Belani, 2008). Targeted drugs, such as angiogenesis inhibitors, epidermal growth factor receptor inhibitors, anaplastic lymphoma kinase inhibitors, and immunotherapy drugs, that act via T cells, eventually can shrink tumors for several months only and are associated with side effects (Silva et al., 2017). Therefore, treatment of radioiodine refractory thyroid cancer and chemoresistant NSCLC remains challenging and new targets and therapeutic substances are desperately needed.

One promising strategy for targeted cancer therapy is delivery of foreign toxic molecules specifically to tumor cells (Walther et al., 2012). Bacterial toxins, as attractive candidates, demonstrated efficient cell-killing capacity in several in vitro and in vivo studies (Dang et al., 2001; Michl and Gress, 2004; Morin, 2005). Employment of pore-forming bacterial toxins, such as *Clostridium perfringens* enterotoxin (CPE) (Minton, 2003; Walther et al., 2012), enables specific targeting of their receptors, which are frequently expressed on cancer cells’ surface. Thereby, the strategy has a great potential to target cancer cells, while minimizing side effects on normal cells.

*Clostridium perfringens* enterotoxin, mainly associated with food poisoning, is released by anaerobic Gram-positive *C. perfringens* type A strains. CPE is a β-pore-forming toxin, consisting of 319 amino acids (35 kDa) and two functional domains with a known structure (pdb: 2XH6, Briggs et al., 2011, pdb: 3AM2, Kitadokoro et al., 2011). CPE-mediated cytotoxicity has been studied and described thoroughly. The procedure starts with CPE binding to its receptors (claudins) on the plasma membrane via its C-terminal domain (cCPE) (McClane, 2001; Veshnyakova et al., 2010), whereas the N-terminal domain inserts into membrane and participates in cytotoxic pore formation allowing rapid Ca\(^{2+}\)-influx leading to cell death (Chakrabarti and McClane, 2005; Eichner et al., 2017). In contrast to full length CPE, the C-terminal domain of CPE (amino acids 194–319, cCPE) is not toxic (Kokai-Kun and McClane, 1997), but maintains binding to claudins (McClane, 2001). Claudins (Cldn, 27 family members) constitute tight junctions (TJs) which regulate paracellular permeability across epithelia. CPE interacts only with a subset of claudins. It binds with high affinity (Kₐ ~ 10 nM) to Cldn3, Cldn4, Cldn6, Cldn7, and Cldn9; with medium affinity to Cldn8, Cldn14, and Cldn19; and with low affinity to Cldn1 and Cldn2, but does not bind to Cldn5, Cldn10 to Cldn13, Cldn15 to Cldn18, and Cldn20 to Cldn24 (Bocsik et al., 2016; Veshnyakova et al., 2010).

In carcinoma cells, claudins are usually mislocalized out of TJs (extrajunctional) and often deregulated (Kwon, 2013), thereby not necessarily contributing to TJ sealing and paracellular barrier regulation. Many epithelial tumors exhibit increased claudin expression (Kominsky et al., 2004; Long et al., 2001; Lu et al., 2013; Michl et al., 2001; Santin et al., 2007; Soini and Talvensaari-Mattila, 2006), which has been discussed as potential marker in oncology (Long et al., 2001). Claudin upregulation is assumed to benefit tumor progression by promoting cell migration, invasion, and metastasis (Jian et al., 2015). In addition to such aberrant expression, extrajunctional mislocalization of claudin proteins may contribute to their role in tumorigenesis (Boireau et al., 2007).

In case of thyroid cancer (Zwanziger et al., 2015) and NSCLC, overexpression (Jung et al., 2009; Sun et al., 2016) and extrajunctional mislocalization of Cldn1, with impact on cell-cell contacts and proliferation, is a specific hallmark. Expression of Cldn1 was demonstrated in PTC, papillary microcarcinoma primary tumors, and lymph node metastases (Nemeth et al., 2010) and is assumed to be a prognostic factor for patients with lung adenocarcinoma (Sun et al., 2016). This makes Cldn1 a promising target for therapeutic approaches.

Several studies have suggested CPE as a biologic for treatment of tumors overexpressing claudins (Black et al., 2015; Kominsky et al., 2007; Morin, 2007; Veshnyakova et al., 2010). Dependence of CPE-mediated cytotoxicity on expression of CPE-sensitive claudins was shown in numerous studies (Eichner et al., 2017; Fujita et al., 2000; Robertson et al., 2010; Sonoda et al., 1999), including claudin knockdowns (Casagrande et al., 2011; Pahle et al., 2017; Tanaka et al., 2018).

However, employment of wild-type CPE (CPEwt) for cancer treatment is restricted to carcinomas, which express CPEwt-binding claudins (e.g., Cldn3, Cldn4). In addition, extrajunctional CPE-sensitive claudin molecules are also present on normal epithelia, at least to a minor extent. This can result in side effects during
CPE treatment. To overcome these difficulties, we modified CPE for the first time to adjust its claudin-binding properties to the claudin expression profile of certain cancer types containing claudin subtypes that are not bound by CPEwt.

Here, we demonstrate expansion of CPE-based oncoleaking strategy specifically for tumor types overexpressing claudins, which are not CPE receptors such as Cldn1 by design and use of CPE mutants: In vitro and in vivo, tumor growth of PTC (K1 cells), overexpressing mainly Cldn1, but not Cldn3 and Cldn4, was efficiently reduced by Cldn1-binding CPE-variant S231R/S313H (CPE-Mut3), but not by CPEwt. In addition, we show that CPE variants suppress growth of NSCLC tumors in a claudin-directed manner.

2. Materials and methods

2.1. Plasmids

Plasmid encoding pGEX-4T-CPE194-319 carrying cCPE with N-terminal GST-fusions was described (Veshnyakova et al., 2012b). Single or multiple substitutions (N218Q, S231R, K283R, S305P, Y306A, Y306W, S313H, and L315A) were generated by site-directed mutagenesis of pGEX-4T1-CPE194-319, as described earlier (Winkler et al., 2009).

For expression as N-terminal 6xHis-fusion, CPE cDNA was subcloned from vector pCpG-optCPE (Walther et al., 2012) as described earlier (Eichner et al., 2017). Site-directed mutagenesis to generate full lengths CPE-Y306W/S313H (Mut1), CPE-S231R (Mut2), CPE-S231R/S313H (Mut3), CPE-S231R/Y306W/S313H (Mut4), CPE-S231R/Y306W/S313H (Mut5), CPE-S231R/Y306W/S313H (Mut6), CPE-S231R/Y306W/S313H (Mut7), CPE-S231R/Y306W/S313H (Mut8), and CPE-Y306W/S313H (Mut9) was performed as described (Winkler et al., 2009). Plasmids based on pEYFP-N1 encoding human Cldn1-YFP, Cldn2-YFP, Cldn5-YFP, Cldn6-YFP, Cldn7-YFP, murine Cldn3-YFP, as well as plasmid pEGFP-Cld4 encoding human Cldn4 with N-terminal GFP (Protze et al., 2015) and plasmid encoding human Cldn1 with N-terminal FLAG (Veshnyakova et al., 2012a) have been described previously.

2.2. Expression and purification of cCPE and CPE constructs

GST-cCPE constructs were expressed and purified as described (Protze et al., 2015). Labeling according to Table S1.

6xHis-CPE was expressed in Escherichia coli TOP10 (Thermo Fisher Scientific, Waltham, MA, USA) and purified from lysates using Ni-NTA-Agarose (Qiagen GmbH, Hilden, Germany), as described earlier (Eichner et al., 2017). For negative control, preparations from bacteria transformed with vector containing CPE insert in antisense – and thus not expressing any CPE – were carried out in parallel, as described earlier (Eichner et al., 2017).

2.3. Cell culture

All cell lines were purchased from Sigma-Aldrich (Taufkirchen, Germany). Native HEK293 (HEK) cells and HEK cells, stably transfected with Cldn1-7, were cultured as described elsewhere (Protze et al., 2015). PC-9 and Nthy-ori 3-1 cells were cultivated in RPMI (10% FBS; 1% penicillin/streptomycin, P/S), K1 – in DMEM (10% FBS; 1% P/S), and SK-Mes-1 – in MEM (10% FBS; 1% P/S, 1% nonessential amino acids) and were grown in a 5% CO2 atmosphere at 37 °C.

2.4. CPE transfection

When cells seeded on poly-L-lysine (Sigma-Aldrich, St. Louis, MO, USA) precoated 96-well plates reached 80% confluency, they were transiently transfected with 0.1 µg DNA of CPE constructs and vector with anti-sense CPE sequence (as negative control) using Viatect (Promega, Madison, WI, USA).

2.5. MTT cytotoxicity assay

For MTT ((3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide; Sigma-Aldrich, USA) cytotoxicity assay cells were seeded 80% confluent on 96-well plates precoated with poly-L-lysine. On next day, cells were preincubated at 37 °C, 5% CO2 for 1 or 24 h, with variable dilutions of cCPE or CPE preparations or 0.01% (v/v) Triton X-100 (background correction) before medium was replaced by medium without phenol red containing 1.25 mM MTT. Two hours later, cells were treated with 5% (v/v) Triton X-100 in 2-propanol for 20 min and absorption was measured at 560 nm.

2.6. Cellular binding assay

Native claudin-negative HEK cells are a suitable model to test specific targeting of single claudins, when those are expressed exogenously (Protze et al., 2015). Two days after transient transfection or 1 day after...
plating of stable lines, HEK cells expressing one of the tested claudins (Cldn1-7) were incubated with 0.5 µg·mL⁻¹ GST-cCPE constructs (30 min, 37 °C) in 24-well plates (Sigma-Aldrich, USA). Amount of bound cCPE was detected as described elsewhere (Protze et al., 2015).

2.7. Cell lysis and western blotting
K1, Nthy-ori 3-1, PC-9, and SK-Mes-1 cells were seeded in 25 cm² cell culture flasks (Greiner Bio One, Kremsmünster, Austria). After reaching confluency, cells were washed and harvested, and extracted membrane protein fraction was analyzed as described elsewhere (Protze et al., 2015). Proteins were detected using specific antibodies against Cldn1-9 or with anti-β-actin (Thermo Fisher Scientific), respectively, and visualized by luminescence imaging (Lumi-Imager, Roche, NY, USA).

2.8. Structural bioinformatics and molecular modeling
Homology models of claudin–cCPE complexes were built based on Cldn4–cCPEwt complex (PDB ID: 5B2G, Shinoda et al., 2016). All manipulations, optimizations of models, were handled as described elsewhere (Neuhaus et al., 2018).

2.9. In vivo CPE application
For cell line-derived subcutaneous xenotransplant (CDX) tumor models, 5 × 10⁵ PC-9 cells or 1 × 10⁶ K1 cells were injected subcutaneously into female NOG mice (n = 5 animals per group). Tumor volume (TV, calculated according to formula 0.5 × length × width²) and body weight were determined at least twice weekly. When tumors reached mean volume of 0.14–0.17 cm³, recombinant CPE was injected intratumorally in anesthetized animals. In total, 20 µg of recombinant CPE was applied by 10 injections (daily dose of 0.04 µg CPE·µL⁻¹ 0.9% NaCl). During treatment, TV was measured at days 11, 14, 18, and 21 after injection of PC-9 cells or at days 18, 21, 25, and 28 after injection of K1 cells. Animals were sacrificed for tumor removal and further analysis. All experiments were performed at EPO GmbH, Berlin, Germany.

2.10. Solid tumor tissue dissection
Shock frozen tumor tissues were fixed with Tissue-Tek Medium (Sakura, Staufen, Germany) and dissected with cryostat into cryosections each of 10 or 18 µm thickness, which were transferred onto cover slides.

2.11. Hematoxylin and eosin staining
For morphological evaluation of 18 µm thick tissue sections, hematoxylin and eosin (HE) staining was performed. Staining procedures were performed by standard protocols (Fischer et al., 2008). All samples were digitally scanned and viewed using Aperio ScanScope AT2 system (Leica Biosystems, Wetzlar, Germany) and QUPATH software (Bankhead et al., 2017). Necrotic areas were calculated by determination of the whole tissue area vs necrotic tissue area using IMAGEJ (open source software, https://imagej.net/) in triplicates of two samples per group. Necrotic area in % related to the whole tissue area is shown.

2.12. Immunohistochemistry of human thyroid samples
Thyroid samples were obtained from patients undergoing thyroid surgery for PTC. For Cldn1 staining, paraffin-embedded tissue sections of 10 PTC were studied. Classification of thyroid nodules was performed by pathologists according to World Health Organization criteria. Cldn1 staining with anti-Cldn1 antibody was performed as described previously (Zwanziger et al., 2015). All samples were digitally scanned and viewed using Aperio ScanScope AT2 system and QUPATH software.

2.13. Statistics
Data are expressed as mean ± SEM. Statistical analyses were performed with GRAPHPAD PRISM version 5.0 (San Diego, CA, USA) using one-way or two-way ANOVA and Bonferroni’s adjustment for multiple comparisons.

3. Results

3.1. Generation of cCPE variant with improved Cldn1 binding
We first aimed to create variants of the nontoxic claudin-binding domain of CPE (cCPE) with increased Cldn1 binding. Mutation S313H in cCPE was previously shown to improve Cldn1 binding and enable Cldn5 binding (Protze et al., 2015; Takahashi et al., 2012).

To further improve Cldn1 and Cldn5 binding of cCPE-Mut1 (cCPE-S313H), we generated models of claudin–cCPE–S313H interaction (Fig. 1A–C). This
pointed us to substitution of S231 to Arg to potentially enhance Cldn1- (Fig. 1B) and Cldn5 binding (Fig. 1C). According to our models, S231R in cCPE (cCPE-Mut2) should allow formation of hydrogen bonds with Q146 and E147 in Cldn1 improving Cldn1-binding properties of cCPE (Fig. 1B) and with E76 and E146 enabling interaction with Cldn5 (Fig. 1C). Furthermore, it potentially enhances binding to Cldn2 by interacting with D76 which corresponds to E76 in Cldn5.

In sum, molecular models suggests that mutation S231R increases the interaction with Cldn1 and Cldn5. Mutants that previously showed effects on interaction with Cldn1 and Cldn5 (N218Q, Neuhaus et al., 2018; Y306W and S313H, Protze et al., 2015) were here tested in the following combinations: The model-guided recombinant cCPE variants Mut1 (cCPE-S313H), Mut2 (cCPE-S231R), Mut3 (cCPE-S231R/S313H), Mut5 (S231R/Y306W/S313H), Mut6 (N218Q/Y306W/S313H), Mut7 (N218Q/S231R/S313H), Mut8 (N218Q/S231R/Y306W/S313H), Mut9 (cCPE-Y306W/S313H), and negative control (cCPE-Y306A/L315A) not binding to claudins (Protze et al., 2015; Table S1) were expressed in E. coli, and purified as previously reported (Protze et al., 2015; Veshnyakova et al., 2012b). Binding of these cCPE variants toward Cldn1 was tested on HEK cells transiently transfected with Cldn1-YFP (Fig. 2A). Single substitutions Mut1 and Mut2 significantly enhanced binding toward Cldn1 and boosted it further, when combined in double mutant Mut3. Moreover, combining single mutation Mut2 with other double mutations resulting in triple mutations cCPE-Mut5 or cCPE-Mut7 increased binding to Cldn1, too. Four substitutions (cCPE-Mut8) showed intermediate effect. Mut6 was employed as additional negative control, since it is known to decrease Cldn1 binding, but to increase Cldn5 binding of cCPE (Neuhaus et al., 2018). In summary, the data showed that cCPE-Mut3 has the best binding properties toward Cldn1.

To test whether cCPE candidate mutations (Mut3 and related Mut1/Mut2, Table S1) influence binding properties toward other claudins, HEK cells stably expressing YFP-tagged single claudins (Cldn1, Cldn2, Cldn3, Cldn5, Cldn6, or Cldn7) or GFP-tagged Cldn4 were employed in cellular binding assay. The YFP- or GFP-tag located intracellularly did not influence the extracellular interaction between claudins and cCPE variants (Veshnyakova et al., 2012b; Winkler et al., 2009). As predicted by modeling, compared to cCPEwt, cCPE-Mut3 bound significantly stronger to Cldn1, Cldn2, and Cldn5 (Fig. 2B,C,F), but weaker to Cldn4 and Cldn6 (Fig. 2E,G). There was no change in binding to Cldn3 (Fig. 2D).
3.2. CPE-Mut3 enables Cldn1-directed cytotoxicity

Next, substitutions Mut1 and Mut2 were introduced into His-tagged full length CPE resulting in CPE-Mut3 to investigate its Cldn1-related cytotoxicity. For comparison, Mut4 (S305P/S307R/S313H), previously shown to increase binding of cCPE to Cldn1 and other claudins, similar as S313H (Protze et al., 2015; Takahashi et al., 2012), was also introduced into full length CPE. CPEwt, CPE-Mut3, CPE-Mut4, and CPE-negative control (Y306A/L315A, not interacting with claudins, Eichner et al., 2017) were applied to nontransfected and stably Cldn1-FLAG-transfected HEK cells. Nontransfected HEK cells were insensitive to any of the tested full length CPE variants (Fig. 3A). In contrast, Cldn1-FLAG-expressing HEK cells were highly sensitive to CPE-Mut3, which strongly reduced cell viability already at low concentrations (0.2 µg·mL⁻¹, Fig. 3B). The broad specificity binder CPE-Mut4 had to be applied in 10-fold higher concentrations – 2 µg·mL⁻¹ to be as cytotoxic as CPE-Mut3 (Fig. 3B). CPEwt or CPE-negative control did not reduce cell viability for Cldn1-FLAG-expressing HEK cells significantly.

Thus, CPE-Mut3, but not other CPE variants, enables efficient Cldn1-directed cytotoxicity. Similarly, structure-based mutagenesis of CPE was used to enable Cldn5-directed cytotoxicity or to narrow down cytotoxicity toward Cldn4 (Fig. S1). Mechanistically, these CPE variants mediate cytotoxicity as CPEwt by induction of Ca²⁺-influx (Fig. S2).

3.3. Expression of endogenous claudins in PTC and NSCLC cell models

We aimed to test cytotoxicity of Cldn1-binding CPE variants on thyroid and lung cancer cell lines, such as

![Fig. 2. Double mutation S231R/S313H (Mut3) increases claudin binding of cCPE. (A) Binding assays with transiently Cldn1-transfected HEK cells revealed that cCPE-Mut3 is the strongest interaction partner of Cldn1 in comparison with the other cCPE variants. Binding assays with HEK cells stably transfected with Cldn1-YFP (B), Cldn2-YFP (C) Cldn3-YFP (D), Cldn4-GFP (E), Cldn5-YFP (F), Cldn6-YFP (G), or Cldn7-YFP (H) showed that cCPE-Mut3 binds stronger to Cldn1, Cldn2, and Cldn5, then CPEwt. Similarly to Cldn1-transfected HEK cells, binding assays with PTC model cell line K1 cells and Nthy-ori 3-1 (Nthy-ori) thyroid follicular epithelial cells (I) showed strongest binding for cCPE-Mut3. cCPE bound stronger to K1 than to Nthy-ori cells. (J) cCPE-Mut3 and cCPEwt bound stronger than cCPE-negative control to PC-9 and SK-MES-1 cells. cCPE-Mut3 and CPEwt bound stronger to PC-9 than to SK-MES-1 cells. Cells were incubated for 30 min with different GST-cCPE constructs (0.5 µg·mL⁻¹), washed, and the bound cCPE was detected via anti-GST-R-phycoerythrin antibodies. The signal was normalized to cell number (A, I, J) or claudin expression level (B-H, YFP- or GFP signal), and the binding of cCPE mutants relative to cCPEwt was calculated. One-way ANOVA, * vs CPEwt or as indicated, ● vs CPE-negative control, □ vs treatment in low claudin-expressing cells (K1 vs Nthy-ori and PC-9 vs SK-MES-1, respectively). n ≥ 3. *, P < 0.05; **, P < 0.01; ***, P < 0.001; ****, P < 0.0001.](image)
K1 cells (PTC) and Nthy-ori 3-1 cells (transformed from normal human thyroid follicular epithelial cells), PC-9 (lung adenocarcinoma), and SK-Mes-1 (lung squamous-cell carcinoma). Expression of Cldn1, as well as of other claudins (Cldn2 to Cldn9), in these cell lines was analyzed by western blot (Fig. 4A). For K1 and Nthy-ori 3-1 cells, expression analysis (Fig. 4A) revealed predominant Cldn1 expression with higher Cldn1 expression in K1 cells. This claudin expression matched to the one in human PTC tissue for which pronounced plasma membrane staining of Cldn1 was observed (Fig. 4B). In normal human thyroid tissue, Cldn1 was moderately expressed in plasma membrane and cytoplasm (Fig. 4C; Zwanziger et al., 2015). Tested lung cancer cell lines expressed not only Cldn1, but also Cldn3, Cldn4, and Cldn7 (PC-9 cells) or Cldn3 (SK-Mes-1 cells). Since Cldn1 expression in PC-9 cells was higher than that of SK-Mes-1 cells, PC-9 cells were used as model for NSCLC for further experiments. K1 cells were chosen as model for PTC and Nthy-ori 3-1 cells as thyroid follicular epithelial cell model.

3.4. CPE-Mut3 reduces cell viability of thyroid cancer cells in vitro

First, we tested binding of nontoxic cCPE variants to K1 and Nthy-ori 3-1 cells expressing Cldn1. Similarly as found for HEK-Cldn1 cells (Fig. 2A), cCPE-Mut3 bound stronger than other cCPE variants to both cell lines (Fig. 2I). Furthermore, stronger binding of cCPE-Mut3 (relative to cCPEwt) to K1 compared with Nthy-ori 3-1 cells correlated with higher Cldn1 expression in K1 cells (Fig. 4A). The data showed that Mut3 enables binding of cCPE to Cldn1-expressing thyroid cancer cells. Consequently, cytotoxicity of full length CPE-Mut3 was tested on Nthy-ori 3-1 and K1 cells using MTT assays. After 24-h incubation with CPEwt, CPE-negative control, CPE-Mut3, and CPE-Mut4, viability of Nthy-ori 3-1 cells was not affected (Fig. 5A). In contrast, incubation of K1 cells with the Cldn1-binders CPE-Mut3 and CPE-Mut4 (Fig. 5B, green and pink) reduced cell viability. At highest concentration, CPE-Mut3 reduced K1 cell viability remarkably to about 20% of negative control levels, whereas CPE-Mut4 decreased it to about 80% of control levels, only. The CPE-negative control and CPEwt (Fig. 5B, black) did not have any toxic effect on K1 cells.

To further verify that CPE-mediated cytotoxicity depends on presence of claudins on surface of K1 cells, K1 cells were incubated simultaneously with both non-cytotoxic cCPE (wt or Mut3) and cytotoxic full length CPE-Mut3 in same molar concentrations. cCPE-Mut3 bound to Cldn1 on the surface of K1 cells and thereby protected them completely from cytotoxic effect of full length CPE-Mut3 (Fig. 5B, blue). In contrast, due to poor interaction of CPEwt with Cldn1, it could not fully protect K1 cells from CPE-Mut3-mediated cytotoxicity (Fig. 5B, orange).

Thus, unlike CPEwt and the broad specificity binder CPE-Mut4, the designed CPE-Mut3 strongly reduced...
cell viability selectively in K1 cells overexpressing Cldn1 \((in \text{ vitro} \text{ PTC model})\). The insensitivity of Nthy-ori 3-1 cells to CPE-Mut3 is likely due to their low Cldn1 expression and suggests that CPE-Mut3-mediated cytotoxicity could potentially be restricted to Cldn1-overexpressing malignant PTC.

### 3.5. CPE variants are cytotoxic for PC-9 lung cancer cells

Similar as for thyroid follicular epithelia and PTC cells, we tested binding of nontoxic cCPE variants to PC-9 and SK-MES-1 lung cancer cells. cCPEwt and cCPE-Mut3 bound much stronger to PC-9 cells than the cCPE-negative control (Fig. 2J). cCPEwt and cCPE-Mut3 bound stronger to PC-9 cells than to SK-MES-1 cells. Nevertheless, cCPE-Mut3 bound stronger than cCPEwt and the latter stronger than the eCPE-negative control to SK-MES-1 cells (Fig. 2J). cCPE binding to the different cell lines correlates to their respective claudin expression profile and level (Fig. 4A). To investigate the cytotoxic effect of CPE variants on lung cancer cells, SK-MES-1 and PC-9 cells were incubated with CPE variants for 1 h. In contrast to the CPE-negative control, CPEwt and cCPE-Mut3 drastically reduced cell viability. Cells were either incubated with CPEwt, CPE-negative control, CPE-Mut3, or CPE-Mut4 or simultaneously treated with cCPEwt or cCPE-Mut3 and CPE-Mut3. Afterward, MTT assay was performed. In competition assay, simultaneous incubation with both nontoxic cCPE-Mut3 and full length CPE-Mut3 (blue line) protected K1 cells from CPE-Mut3-mediated cytotoxicity (green line). cCPEwt added together with CPE-Mut3 (orange line) showed just a weak protective effect, and CPE-negative control (purple line) and CPEwt (black line) did not affect K1 cells. (C) SK-MES-1 cells were incubated for 1 h with CPE variants (wt, Mut3 and negative control) at different concentrations followed by MTT assay. CPEwt and CPE-Mut3 reduced cell viability to \(~50\%\). (D) PC-9 cells expressing multiple claudins were efficiently attacked by CPEwt, CPE-Mut3, and CPE-Mut4. Cells were incubated for 1 h with CPE variants (wt, Mut3, Mut4, and negative control) at different concentrations followed by MTT assay. Where indicated, cells were preincubated for 1 h with nontoxic cCPE (wt or Mut3) before CPE-Mut3 application. Partial inhibition effect at concentrations lower than 0.2 \(\mu\)g-ml\(^{-1}\) and full inhibition at higher concentrations (blue, orange lines) indicated that low cCPE concentration was not sufficient to occupy all CPE receptors. (E) PC-9 cells were transfected with DNA (0.1 \(\mu\)g) of CPE constructs, and 24 h later, MTT cytotoxicity assay was performed. All CPE constructs, except for CPE-negative control, were toxic similarly to 0.1\% Triton X-100. Application of growth medium with 0.1\% Triton X-100 was used as control for cell lysis in (A–E). n = 3–11 (K1 cells + Mut4 n = 1), one-way ANOVA with Bonferroni multiple comparisons significant vs CPE-negative control (at the same concentration) \(*P < 0.01; ***P < 0.001; ****P < 0.0001\) (A–D), or one-way ANOVA with Bonferroni multiple comparisons significant vs ViaFect, \((n = 4) *P < 0.05; **P < 0.01; ***P < 0.001\) (E).
Mut3 decreased cell viability of SK-MES-1 cells at concentrations ≥ 0.1 µg·mL⁻¹ (Fig. 5C). For PC-9 cells expressing multiple claudins (Fig. 4A) and showing strong cCPE binding, incubation with CPEwt, Mut3, and Mut4 strongly decreased cell viability at concentrations ≥ 0.1 µg·mL⁻¹ (Fig. 5D, green dotted line). At concentrations ≥ 1 µg·mL⁻¹, these CPE variants reduced cell viability similarly to the level of cell lysis positive control (0.1% Triton X-100, about 20%, Fig. 5D, magenta dotted line). As expected, CPE-negative control did not reduce cell viability even at high concentrations. The stronger CPE sensitivity of PC-9 compared to SK-MES-1 cells correlated to their claudin expression profiles and levels (Fig. 4A).
Competition cytotoxicity assay with nontoxic cCPE variants demonstrated that full length CPE-Mut3 requires claudin molecules on the plasma membrane. PC-9 cells were preincubated with cCPEwt or cCPE-Mut3 for 1 h before 1-h incubation with the same molar concentration of full length CPE-Mut3. Preincubation of PC-9 cells with cCPEwt or cCPE-Mut3 led to competition for claudin binding and at high concentrations strongly inhibited reduction in cell viability mediated by CPE-Mut3 (Fig. 5C, blue and orange), indicating that protective effect of cCPE depends on its concentration. Thus, CPE-Mut3-mediated cytotoxicity depends on claudins on the surface of PC-9 cells. The data showed that claudin-binding CPE variants can efficiently attack lung cancer cells expressing multiple claudins.

### 3.6. CPE application via DNA transfection

As an alternative application route, CPE transfection (Walther et al., 2012) was used for comparison. 0.1 µg DNA of CPE constructs or controls were transiently transfected into PC-9 cells, and 24 h later, cytotoxicity assay was performed. MTT assays revealed similar results as with recombinant CPE: CPEwt, CPE-Mut3, and CPE-Mut4, but not the nonbinding CPE-negative control strongly reduced cell viability (Fig. 5E). Our data support the rigorous claudin dependency of CPE toxicity independently of the route of application as shown before (Walther et al., 2012).

Thus, two independent approaches of CPE application (recombinant protein and DNA transfection) demonstrated for PC-9 cells (a) claudin-dependent cytotoxicity of CPE and (b) that all claudin-sensitive CPE variants (CPEwt, CPE-Mut3 and CPE-Mut4) reduced cell viability. The latter can be explained by the fact that PC-9 cells do not only express Cldn1, but also Cldn3, Cldn4, and Cldn7 (Fig. 4A), which strongly interact with CPEwt and CPE-Mut4.

### 3.7. CPE treatment reduces tumor growth of thyroid and lung cancer in vivo

Finally, we tested in vivo the effect of CPE variants on tumor growth on CDX models. For establishment of subcutaneous tumors, K1 or PC-9 cells were injected into female NOG mice. When tumors reached a mean volume of 0.14–0.17 cm3, 10 intratumoral injections of recombinant CPE (wt or -Mut3) or of vector control preparations were administrated within 10 days (single 2 µg injection daily).

In the PTC K1 xenograft model, during treatment by vector control and CPEwt the tumor was growing strongly to 1.1 ± 0.15 cm3 and to 1.0 ± 0.21 cm3, respectively. In contrast, for CPE-Mut3-treated animals, only minor tumor growth (to 0.28 ± 0.04 cm3) was observed. The study revealed no significant effect of CPEwt treatment, but a very efficient anti-tumoral activity of CPE-Mut3, reflected by reduced tumor growth (14% compared to control) (Fig. 6A). Hence, unlike CPEwt, the CPE variant with increased affinity to Cldn1 binds stronger to PTC cells. This binding is associated with more efficient tumor cell killing, resulting in tumor reduction.

In the PC-9 xenograft model, measurements of TV on days 11, 14, 18, and 21 after beginning of CPE-administration in different treatment groups revealed anti-tumoral activity of both CPEwt and of CPE-Mut3, reflected by respective TVs of 43% and 29% (compared to vector control treatment, Fig. 6B). Here, CPE-Mut3 exerted only slightly improved anti-tumoral effects than CPEwt. Thus, intratumoral CPE treatment is able to reduce TV in lung cancer PC-9 CDX model effectively.

### 3.8. CPE treatment causes necrosis in thyroid and lung tumor

Intratumoral injection of CPE variants reduced significantly TV of K1 and PC-9 xenograft models. HE staining revealed a small amount of 5–10% of necrotic...
areas of K1 tumors treated with vector control and 
PCEwt, whereas CPE-Mut3 application increased 
necrotic areas of K1 tumors to approximately 40% 
(Fig. 6C,D). In PC-9 tumors, necrotic areas of vector 
control treated mice were approximately 23% and 
elevated to 51% and 63% by PCEwt and PCE-Mut3 
application, respectively (Fig. 6C,E). Taken together, 
the in vivo data indicate that PCE treatment reduces 
tumor growth by induction of necrosis.

In thyroid and lung tumor xenograft models, 
immunostaining of claudins and ZO1 did not reveal a 
junctional localization, pointing to absence of intact 
TJ. In thyroid xenograft model, the analysis showed 
strongest CPE and weakest Cldn1 signals in PCE-
Mut3-treated samples (Fig. S3). For lung xenograft 
model PCEwt and PCE-Mut3 treatment, the immunos-
tainings did not reveal a clear change in expression 
and distribution of Cldn3, Cldn4, and Cldn7 (Fig. S3).

4. Discussion

In this study, we used structure-guided mutagenesis of 
PCE to enable for the first time cytotoxic targeting of 
tumors expressing Cldn1 or Cldn5 to which PCEwt 
does not bind considerably. As a proof of principle, 
we showed in vitro and in vivo that claudin-binding 
properties of PCE can be shifted (a) to expand use of 
PCE to targeting of Cldn1-expressing thyroid tumors 
and (b) to potentially reduce PCE side effects by 
matching the binding properties of PCE to the claudin 
expression profile of particular carcinoma types.

This study aimed to overcome the restriction of the 
promising PCE treatment to tumors expressing only 
receptors for PCEwt (Cldn3, Cldn4, Cldn6, Ben-
David et al., 2013; Kominsky et al., 2007; Kominsky 
et al., 2004; Liang et al., 2017; Michl et al., 2001; San-
tin et al., 2005; Walther et al., 2012). We adapted the 
PCE binding properties to other claudins according to 
the expression profile of different carcinomas. In par-
cular, binding to Cldn1 expressed in NSCLC (Jung 
et al., 2009; Sun et al., 2016) and thyroid cancer 
(Zwanziger et al., 2015) was intended. The role of 
Cldn1 in follicular type of thyroid cancer was well 
described (Zwanziger et al., 2015). However, for PTC, 
the most common type of thyroid cancer, the Cldn1 
expression, and its role in pathogeny are currently 
poorly characterized. In this study, we concentrated on 
PTC since this is the most common type of all thyroid 
cancers.

First, we verified if model-guided variants of cPCE– 
the nontoxic claudin-binding domain of PCE – were 
able to interact with Cldn1 to Cldn7. cPCE-Mut3 with 
increased binding to Cldn1 was chosen as the most 

promising candidate for PTC cells’ eradication. Its 
additional ability to interact with Cldn5 is of advan-
tage for potential NSCLC treatment, since NSCLC is 
characterized by upregulation of several claudins 
including both Cldn1 and Cldn5 (Paschoud et al., 2007).

Consequently, Mut3 and, as comparison, Mut4 – 
which was previously shown to improve cPCE binding 
to Cldn1 and Cldn5 – were introduced into cytotoxic 
full length PCE and showed identical claudin speci-
ficity as corresponding cPCE variants. In contrast to 
PCEwt, CPE-Mut3 and CPE-Mut4 were cytotoxic for 
Cldn1-overexpressing but not for native HEK cells. 
This finding demonstrated the ability of novel PCE 
variants to specifically target Cldn1-expressing cells.

Furthermore, in contrast to PCEwt, PCE-Mut3 was 
cytotoxic for K1 thyroid cancer cells expressing 
endogenous Cldn1. For PC-9 lung cancer cells that 
express multiple claudins, apart from PCE-Mut3 also 
PCEwt and PCE-Mut4 mediated cytotoxicity. Finally, 
claudin-specific cytotoxicity was confirmed in vivo on 
CDX models of PTC (K1 cells) and of NSCLC (PC-9 
cells). For the first time, PCE was used to successfully 
reduce growth of lung tumors (PC-9 cells) and its 
Mut3 enabled efficient Cldn1-directed reduction of 
PCT (K1 cells) growth.

Using the same approach of structure-guided muta-
genesis, we also generated PCE-Mut9 and PCE-Mut10 
which enabled efficient Cldn5- and Cldn4-directed 
cytotoxicity, respectively (Fig. S1). Thus, PCE variants 
with claudin-binding properties matching to the clau-
din expression profile of the targeted tumor type have 
a potential to maximize tumor cell eradication and 
minimize side effects on normal claudin-expressing 
cells.

In several studies, high claudin specificity of anti-
claudin antibodies (Cldn1, Yoda et al., 2014; Cldn4, 
Silva et al., 2017; Cldn5, Hashimoto et al., 2017; and 
Cldn18.2, Singh et al., 2017) was used for cancer cell 
targeting. However, recombinant PCE variants as anti-
tumoral tools have several advantages over anti-clau-
din antibodies’ application: (a) cost-effective bacterial 
production of PCE, (b) ability to adjust PCE, by direc-
ted structural modification to target several claudin 
subtypes and thereby target higher number of claudin 
molecules, causing faster and more severe eradicating 
effect, and (c) in PCE, the claudin-targeting and effec-
tor (toxic) domains are already natively combined, 
whereas for other immunotoxins and antibodies target-
ing and toxicity have to be mediated independently.

Moreover, PCE can be applied by cost- and labor-
effective nonviral in vivo gene transfer (Walther et al., 
2012). This results in PCE production in target cells,
causing direct cell killing further enhanced by a toxin-mediated bystander effect. The claudin specificity and dependency of the cytotoxicity mediated by CPE expressed after gene transfer in mammalian cells was demonstrated previously (Pahle et al., 2017; Walther et al., 2012). In the current study, gene transfer of CPE variants mediated a similar toxicity on the NSCLC model in vitro (PC-9 cells) as the recombinant protein (Fig. 5D,E). Thus, the suicide gene transfer approach can be broadened to CPE variants. However, here we applied recombinant CPE for in vivo experiments, since this enabled better control of CPE concentration.

Intratumoral in vivo application of recombinant CPE did not induce general toxin-associated side effects in PC-9 and K1 xenograft models bearing mice, supporting its great therapeutic potential (Kominsky et al., 2007). However, use of CPE for tumor therapy is restricted by the fact that CPE-binding claudins are expressed in numerous tissues and, thereby, there is risk of unwanted cytotoxic damage of normal cells. Nevertheless, most tumor cells are assumed to be more sensitive to CPE than differentiated epithelial cells due to (a) overexpression and (b) higher accessibility of claudins caused by extrajunctional mislocalization of the molecules (Corsini et al., 2018; Eichner et al., 2017) (Fig. S3). In contrast, for example, in colonocytes, claudin accessibility, and in turn CPE-mediated tissue damage, is strongly limited (Eichner et al., 2017). However, better restriction of CPE-mediated cytotoxicity to tumors might be achieved by use of CPE variants with a claudin-subtype specificity optimized to match the claudin (over-) expression profile of defined carcinomas. Nevertheless, extent of side effects due to CPE binding to claudins outside tumors has to be investigated in future in vivo studies with CPE variants.

A potential immune response against CPE could be addressed, for instance, (a) by subsequent use of cytotoxic cCPE-PSIF (protein synthesis inhibitory factor) fusion proteins (Ebihara et al., 2006) or (b) structure-based modification of surface residues of CPE outside of the claudin-binding region.

5. Conclusions

In summary, we showed that CPE can be modified by structure-guided mutagenesis to match the binding properties of CPE to the claudin expression profile of particular carcinoma types. We thereby enabled, as proof of principle, Cldn1-directed cytotoxic targeting of thyroid tumors. The results suggest use of CPE-based biologics for eradication of claudin-overexpressing cancers in a novel cross-entity approach.
