BACKGROUND: Secondary organic aerosols (SOAs) formed from anthropogenic or biogenic gaseous precursors in the atmosphere substantially contribute to the ambient fine particulate matter [PM ≤2.5 μm in aerodynamic diameter (PM2.5)] burden, which has been associated with adverse human health effects. However, there is only limited evidence on their differential toxicological impact.

OBJECTIVES: We aimed to discriminate toxicological effects of aerosols generated by atmospheric aging on combustion soot particles (SPs) of gaseous biogenic (β-pinene) or anthropogenic (naphthalene) precursors in two different lung cell models exposed at the air–liquid interface (ALI).

METHODS: Mono- or cocultures of lung epithelial cells (A549) and endothelial cells (EA.hy926) were exposed at the ALI for 4 h to different aerosol concentrations of a photochemically aged mixture of primary combustion SP and β-pinene (SOAβpin–SP) or naphthalene (SOANAP–SP). The internally mixed soot/SPs were comprehensively characterized in terms of their physical and chemical properties. We conducted toxicity tests to determine cytotoxicity, intracellular oxidative stress, primary and secondary genotoxicity, as well as inflammatory and angiogenic effects.

RESULTS: We observed considerable toxicity-related outcomes in cells treated with either SOA type. Greater adverse effects were measured for SOANAP–SP compared with SOAβpin–SP in both cell models, whereas the nano-sized soot cores alone showed only minor effects. At the functional level, we found that SOANAP–SP augmented the secretion of malondialdehyde and interleukin-8 and may have induced the activation of endothelial cells in the coculture system. This activation was confirmed by comet assay, suggesting secondary genotoxicity and greater angiogenic potential. Chemical characterization of PM revealed distinctive qualitative differences in the composition of the two secondary aerosol types.

DISCUSSION: In this study using A549 and EA.hy926 cells exposed at ALI, SOA compounds had greater toxicity than primary SPs. Photochemical aging of naphthalene was associated with the formation of more oxidized, more aromatic SOAs with a higher oxidative potential and toxicity compared with β-pinene. Thus, we conclude that the influence of atmospheric chemistry on the chemical PM composition plays a crucial role for the adverse health outcome of emissions.

Introduction

Over the past decades, the impact of fine particulate matter [PM ≤2.5 μm (PM2.5)] on the global burden of disease has gained substantial attention. Epidemiological cohort studies have found significant correlations between the exposure to PM2.5 and substantial effects on human health, such as respiratory and cardiovascular diseases, and increased morbidity and mortality (Brook et al. 2010; Cohen et al. 2017; Pope et al. 2020). It is well accepted that the toxicity of PM2.5 varies between its sources and formation pathways. However, it is still largely unknown which PM properties—such as size, mass, shape, surface properties, or chemical composition—induce biological responses (Burkholder et al. 2017; Park et al. 2018; Wyzga and Rohr 2015). Furthermore, our knowledge is mostly limited to the effects of collected airborne particles under submerged exposure conditions rather than the direct deposition and interaction of aerosols with cell cultures (Ihantola et al. 2020; Oeder et al. 2015). Submerged exposures do not reflect the physiological condition of airway barriers because inhalation occurs by aerosol deposition onto airway epithelial cells that form, together with, for example, endothelial cells and basal membranes, a tissue layer enabling gas exchanges between the lungs and the blood circulation (Barosova et al. 2021). Air–liquid interface (ALI) aerosol exposures offer several advantages compared with submerged conditions. These include the preservation of the physicochemical characteristics of airborne PM and a higher sensitivity both in terms of effective doses, which are lower at the ALI, and in terms of transcripts regulation and protein enrichment, which are more pronounced in alveolar epithelial A549 cells.
exposed at ALI compared with submerged exposures (Hilton et al. 2019; Lenz et al. 2013; Loreti et al. 2016). It has been shown that ALI-cultured A549 cells retain more of the usual patterns of tight junction proteins, such as occluding, claudin-2, and zonula occludens-3, as well as show lower permeation coefficient values than the submerged cells, resulting in a clear and tighter epithelial phenotype (Rothen-Rutishauser et al. 2008).

Atmospheric aerosol particles may originate from primary sources (primary aerosols), but they are also formed and altered by oxidative gas-to-particle conversion in the atmosphere (secondary aerosols) as well as complex multiphase chemistry (aged primary aerosols) (Hallquist et al. 2009). The sources contributing to the global primary aerosol load are manifold and from both anthropogenic and natural origin, including industrial processes, traffic, sea spray, and wildfire burnings. Soot, or its related entities black carbon (BC) and elemental carbon (EC), is released from both anthropogenic (e.g., traffic, residential heating, industry) and naturally occurring (e.g., wildfire) combustion processes (Bond et al. 2013). In contrast to BC and EC, the term soot particles (SPs) is less specific and does not refer to carbon atoms only. Instead, it is described as black particles that can enter the atmosphere through combustion processes (Andreae and Gelencsér 2006), so it also includes organic and inorganic PM. SP has impacts on human health upon inhalation (Janssen et al. 2011); however, freshly emitted SP become very quickly coated by secondary aerosols in ambient air (Moore et al. 2014). Secondary aerosols are generated from volatile precursors by atmospheric oxidants, such as hydroxyl (OH), ozone (O_3), and nitrate radicals, or by photolysis in the atmosphere (Hallquist et al. 2009; Shakya and Griffin 2010). Secondary organic aerosols (SOAs) from the oxidative conversion of volatile organic compounds (VOCs) may increase levels of ambient PM_2.5 considerably, causing severe haze pollution episodes (Huang et al. 2014). Naphthalene and β-pinene were found to be substantial contributors to the anthropogenic (Jia and Batterman 2010) and biogenic (Guenther et al. 2012) global VOC emissions, respectively, with significant potential to form SOAs (Chen et al. 2016; Watne et al. 2017).

Naphthalene represents the smallest and most volatile polycyclic aromatic hydrocarbon (PAH) and is classified by the International Agency for Research on Cancer as probably carcinogenic to humans (Group 2B) (IARC 2010). It is mainly formed during combustion processes, such as fossil fuel combustion in engines, in particular diesel engines, biomass burning, or tobacco smoking, as well as in the chemical and metal industries (Jia and Batterman 2010; Qian et al. 2021; Wang et al. 2020). Because of its high vapor pressure, naphthalene is mainly in the gas phase at ambient conditions and thus undergoes homogeneous gas-phase reactions in the atmosphere, which can result in products of lower volatility accompanied with their conversion into the particle phase and the generation of SOAs (Williams et al. 2010). β-pinene is a monoterpene, one of the main compounds released by vegetation, such as by various coniferous plants (Faiola et al. 2015; Kleist et al. 2012). Its oxidation leads to substantial yields of SOAs (Sarrafzadeh et al. 2016; Xavier et al. 2019), including the formation of highly oxidized extremely low-VOCs (Ehn et al. 2014). On a global scale, biogenic VOCs largely exceed the emissions of anthropogenic VOCs; however, anthropogenic VOCs may regionally reach higher levels than biogenic VOCs (Guenther et al. 1995). In the case of biogenic VOCs (isoprene, terpenes) toxicity is generally enhanced by photochemical aging; however, there is an unambiguous effect of aging for PAHs and engine emissions (Weitekamp et al. 2020; Xu et al. 2022).

Depending on the size of the PM, their retention in the lung varies. Although inhaled particles between 5 and 10 μm in aerodynamic diameter typically affect only the upper airways and are removed by mucociliary clearance, particles in the range between 1 and 2.5 μm are able to penetrate deep into the respiratory regions and particles <1 μm can easily deposit on alveoli and be retained in the surfactant (Heyder 2004). Moreover, an in vivo study showed that not only can ultrafine PM [PM ≤ 0.1 μm (PM_{0.1})] enter extrapulmonary organs, but particles with an aerodynamic diameter of between 0.2 and 2 μm can also (Li et al. 2019). In addition to the direct harm of particles to the organs, several in vitro studies in human lung epithelial cells have shown that the PM_{2.5} of SOA can trigger inflammation with systemic effects through the release of pro-inflammatory cytokines (Feng et al. 2016), an increase in reactive oxygen species (ROS) (Arashiro et al. 2018), and an impairment of the anti-oxidant system (Arashiro et al. 2018; Deng et al. 2013; Kouassi et al. 2010; Longhin et al. 2013). In response, oxidative stress further triggers inflammatory and mutagenic responses (Dergam et al. 2012; Lin et al. 2017; Longhin et al. 2013; Möller et al. 2014; Riediker et al. 2019). Beyond the size of ambient PM_{2.5}, its chemical composition is assumed to play an important role in the toxicity of the particles (Eaves et al. 2020; Sýkorová et al. 2016). Oxidation flow reactor (OFR) studies have revealed a greater toxic effect of higher photochemically aged α-pinene- and naphthalene-derived SOAs on A549 cells compared with their SOAs of lower photochemical age, which was attributed to the increased formation of ROS (Chowdhury et al. 2018, 2019).

Within the project aeroHEALTH (https://www.aerohealth.eu), the present study aimed to investigate the toxicological impacts of two model systems representing air pollution by primary combustion emissions (e.g., SPs) and atmospheric processing of a typical anthropogenic (e.g., naphthalene) or biogenic (e.g., β-pinene) VOC precursor. In the used experimental setup, the SOAs were generated in an OFR in the presence of freshly formed combustion soot, leading to coating SPs with condensed organic matter from naphthalene (SOA_{SP-AP}-SP) and β-pinene (SOA_{SP-SP}-SP), respectively. Two different cell culture systems were exposed to these aerosols at the ALI. Increasing epidemiological and experimental evidences show that environmental exposure may disturb airway intercellular communication by indirect mechanisms, such as the release of inflammatory cytokines, or by direct mechanisms, including particles translocating from the lung into the circulation (Peters et al. 2021; Wang et al. 2019). Especially in the alveolar region, PAHs contained in the gas phase or detached from the particle surface may be displaced across the airway barriers and reach cells and secondary tissues that are not directly exposed (Låg et al. 2020). In view of the important role of these mechanisms, A549 human alveolar epithelial cells were grown either as a monolculture on an insert membrane or as a coculture model with microvascular endothelial EA.hy926 cells on the basolateral side of the membrane to mimic the blood–air barrier and to evaluate cell-to-cell interplay. We performed assays testing for aerosol-induced oxidative stress, inflammation, geno- and cytotoxicity, as well as to elucidate possible secondary effects derived from cellular interplay, according to adverse outcome pathways (Halappanavar et al. 2020). With this setup, we aimed to address the overarching scientific question whether atmospheric aging and the related formation and condensation of SOAs on SPs can increase the toxicity of the particles and whether the SOA precursor plays a decisive role in the biological response.

**Material and Methods**

**Aerosol Generation and Characterization**

**Aerosol generation and sampling setup.** SOAs of either naphthalene (Sigma-Aldrich; 147141-25G; ≥99%) or β-pinene (Sigma-Aldrich; 402753-10G; ≥99%) were produced by mixing their pure vapor with SPs and subsequent processing in an OFR [i.e., a
potential aerosol mass (PAM) reactor) \cite{Bruns2015, Kang2007} for the simulation of atmospheric photooxidation (aging) by OH radicals. In addition, pure SPs were also fed into the PAM reactor without aging and used as the reference control. This was done because SPs and SOA precursors refer to primary compounds, which are simultaneously transformed by atmospheric aging. However, SOA rapidly starts to cover the surface of the SPs, and the particle constitution may be described by a core–shell model. Only particulate organic species at or near the particle surface are exposed to OH radicals, whereas the soot core of the particle is shielded against heterogeneous oxidation \cite{Lim2017}. Considering the generally slower reaction kinetics of heterogeneous oxidation compared with the homogeneous oxidation involved in SOA formation, we may assume that soot cores are oxidized to a negligible extent. Therefore, fresh SPs, rather than aged SPs, without the addition of SOA precursors were used as the reference. A simplified scheme of the setup is shown in Figure 1.

First, SPs, functioning as a condensation sink for SOAs, were produced by a CAST-Burner \cite{CombustionAerosolStandard, Jing2015} under lean combustion conditions (50 mL/min propane, 0 mL/min MixN2, 1.42 L/min Oxid.Air, and 20 L/min Dil. Air) to minimize the organic content and generate EC-rich particles with a Gaussian size distribution (geometric mean \(\sim 100\) nm). A custom-made porous tube diluter with a variable mass flow-controlled dilution ratio was applied as a first dilution step. Naphthalene or \(\beta\)-pinene vapors were produced using a custom-made diffusion source, placed in a temperature-controlled water bath, using nitrogen (99.999% purity) with a flow rate of 1 L/min. The length and diameter of the diffusion source, as well as the bath temperature, were adjusted for each VOC individually to maintain the same precursor concentration. The bath temperatures for VOC generation were \(\sim 40\)°C for \(\beta\)-pinene and \(\sim 60\)°C for naphthalene. Diameters of the diffusion source were 10 mm for \(\beta\)-pinene (length \(40\) mm) and 25 mm for naphthalene (length \(\sim 5\) mm), with an additional 25 mm of frit to prevent turbulent mixing and reduce diffusion. The targeted VOC concentration of 4 mg/m\(^3\) was adjusted every day before the experiment and verified after the experiment by a flame ionization detector \cite{109A, JUEmEngineering}. The mixture of soot and VOC was humidified during a second dilution step using an ejector diluter \cite{PalasVKL, PalasGmbH} with a fixed 1:10 dilution ratio. Here, humidified air \(\text{moistened by a PermaPure humidifier}\) was produced with 0.3 mL/min nitrogen, containing deuterated butanol (D9-butanol; 98% isotopic purity; Sigma Aldrich) was used as dilution medium. Final concentrations entering the PAM reactor were 1 mg/m\(^3\) soot, 4 mg/m\(^3\) VOC, and 80 ppb V D9-butanol at 40% relative humidity (RH).

The PAM reactor \cite{Bruns2015, Kang2007} refers to an OFR with an internal volume of 15 L and was operated at a flow rate of 8 L/min, resulting in a mean residence time of 113 s. It generates \(O_3\) in situ and, subsequently, OH radicals from irradiating humid air by two ultraviolet (UV)-lamps (BHK Inc.) with emission of deuterium (D) label.

Figure 1. A schematic overview of the aerosol generation, sampling method, and ALI exposure system. SP (CAST soot; 1 mg/m\(^3\)) together with either \(\beta\)-pinene (4 mg/m\(^3\)) or naphthalene (4 mg/m\(^3\)) passed through a PAM reactor for photochemical aging by OH radicals after humidification and appropriate dilution. In addition, pure SP (CAST soot; 1 mg/m\(^3\)) were fed into the PAM reactor without aging and used as the reference control. \(O_3\), which was produced in situ by the PAM reactor, was removed after the reactor by an \(O_3\)-scrubber to a level <10 ppb. State-of-the-art methods characterized the chemical and physical properties of the generated SOA \cite{lineA: TEOM; lineAB: PTR-MS, SMPS, CPC, O3 monitor; lineC: O3 monitor; lineD: Aethalometer, SMPS, AMS, OPROSI, offline sampling (VOC adsorber, TEM, GC x GC-TOFMS)}. Two ALI exposure systems were used in parallel. An optional 1:3 diluter in front of one ALI exposure system and a 1:10 diluter in front of the second ALI exposure system were applied to investigate different dilutions of the aerosol [undiluted (1:1), 1:3, 1:10, and 1:30]. The magnification of a single exposure position illustrates the air flow of the aerosol over the cells growing on the membrane of Transwell inserts and shows aerosol deposition by diffusion. Note: ALI, air-liquid interface; AMS, high-resolution time-of-flight aerosol mass spectrometer; CAST, combustion aerosol standard; CPC, condensation particle counter; \(\Delta p\), change in pressure; GC x GC-TOFMS, comprehensive two-dimensional gas chromatography–time-of-flight mass spectrometer; OH, hydroxy; OPROSI, online particle-bound ROS (reactive oxygen species) instrument; O3, \(O_3\); PAM, potential aerosol mass; PTR-MS, quadrupole proton–transfer reaction mass spectrometer; SMPS, scanning mobility particle sizer; SOA, secondary organic aerosol; SP, soot particle; TEM, Transmission electron microscope; TEOM, tapered element oscillating microbalance; VOC, volatile organic compounds.
lines at 185 and 254 nm. We adjusted the UV lamp power to obtain similar photochemical ages (~3 d) of both types of SOAs, accounting for the different rate constants of naphthalene and β-pinene toward the OH radical ($k_{OH}$ (naphthalene)) = $2.3 \times 10^{-10}$ cm$^3$/s; $k_{OH}$ (β-pinene) = $7.4 \times 10^{-12}$ cm$^3$/s ($Atkinson$ and $Arey$ 2003). Although SOA-precurors and SP were exposed to O$_3$ concentrations of 6.0 ± 0.6 ppm (β-pinene) and 5.4 ± 0.3 ppm (naphthalene) for 113 s, the aging under the described conditions is strongly dominated by OH radical chemistry ($Atkinson$ and $Cartier$ 1984; $Sarrafzadeh$ et al. 2016). Fractional importance of non-OH fate, including photolysis at 185 and 254 nm, as well as reactions with O(1$^3$D), O(3$^3$P), and O$_3$, were found to be comparable to ambient air assessed by the PAM model of Peng et al. (2016). Furthermore, the surface oxidation of SP by O$_3$ is estimated to be negligible based on the kinetic data of Chughtai et al. (2003).

A ceramic honeycomb denuder, impregnated with sodium nitrite was installed downstream of the PAM reactor to remove O$_3$ to a level of <10 ppbV, and monitored by the O$_3$ monitor. In addition, a custom-made porous tube diluter (fixed at a 1:3 dilution) and an ejector diluter (1:10 dilution) (Palas) were installed in the sampling lines guided to the two ALI exposure systems to obtain the different dilution ratios [undiluted (1:1), 1:3, 1:10, and 1:30] for the cell exposures. All dilution steps were conducted with purified compressed laboratory air, compressed by an oil-free compressor (SF4; Atlas Copco) and purified by a modified catalytic converter (737-15; Aaaco), which removed hydrocarbons, including methane, to a concentration of <10 ppbV.

**Online aerosol measurements.** Four sampling points were used for the online aerosol measurements (Figure 1). A detailed description of the respective methods are outlined in the below paragraphs.

**Particle number and particle size distribution.** A scanning mobility particle sizer (SMPS) comprised of an electrostatic classifier (TSI; model 3082) connected to a condensation particle counter (TSI; model 3750) was installed at line D. Multiple charge correction and diffusion loss correction were done using AIM software (version 10.3; TSI). A second electrostatic classifier (TSI; model 3082) connected to a 3025A CPC (TSI) was installed with the option to switch between line A or line B without additional dilution for monitoring the feed and aged aerosol properties.

**BC and particle mass.** A seven-wavelength aethalometer (model Magee AE33; Aerosol d.o.o.) was used at line D to confirm stable SP concentrations, measured as BC at 880 nm, whereas the difference of the PM concentration at 370 and 880 nm, denoted as brown carbon (BrC), confirmed the stable formation of SOA over the whole cell exposure time. In addition, a tapered element oscillating microbalance (TEOM 1400a; Rupprecht & Patashnick Co., Inc.) was used to determine the SP mass concentration at line A and line B. Both instruments had own ejector diluters (1:10 dilution) (Palas), ensuring the appropriate concentrations.

**Photochemical age.** D9-butanol was used as a photochemical clock and was measured before and after the PAM reactor step by a quadrupole proton-transfer reaction mass spectrometer (PTR-MS; Ionicon). With a rate constant of $3.4 \times 10^{-12}$ cm$^3$/s for D9-butanol and a mean PAM reactor residence time of 112.5 s, the OH radical exposure can be calculated and subsequently converted into an equivalent photochemical age ($Barmet$ et al., 2012), assuming an average ambient OH radical concentration of 10$^6$ molecules/cm$^3$ ($Pinn$ et al. 2001). The PTR-MS was installed in parallel to the second electrostatic classifier (switching between line A and line B) and setup in multiple ion detection mode, with an estimated detection limit of 0.5 ppb. For experiments with naphthalene: $m/z$ 21 (primary water ion, [H$18^2$O+H$^+$]), 66 (D9-butanol fragment [M-HDO+H$^+$]), 129 (naphthalene C$_{10}$H$_8$ [M+H$^+$], for quantification), and 159 (naphthoquinone C$_{10}$H$_{12}$O$_2$, [M+H$^+$]) were recorded. For experiments with β-pinene: $m/z$ 21, 66, 137 ([β-pinene [M+H$^+$], for quantification), and 81 ([β-pinene fragment [M-C$_4$H$_6$+H$^+$], as quencher]).

O$_3$, which was formed in situ by vacuum ultraviolet (VUV) radiation at 185 nm, was quantified after a 10-fold dilution with pure nitrogen by an O$_3$ monitor (model O$_3$ 41 M; Environment S. A./Ansysco GmbH) at line B. A second O$_3$ monitor (model APOA 350E; Horiba) was installed at line C to guarantee that no O$_3$ reached the ALI systems.

**Elemental ratios.** A high-resolution time-of-flight aerosol mass spectrometer (AMS; Aerodyne Inc.) (DeCarlo et al. 2006) was operated at line D to determine ratios of the elements O/C and H/C, the total mass concentration, and a size distribution of the nonrefractory organic chemical composition. The instrument was run with a vaporizer temperature of 560°C, with an averaging time of ∼4 min. The resulting mass spectrum was analyzed in the $m/z$ range of 12–220 amu because the fractions >200 amu have little to no impact on the total organic concentration or the elemental composition, given that we observed no $m/z >300$ amu. Calibrations were preformed weekly using dried 350-nm ammonium nitrate particles, size selected based on mobility diameter with a differential mobility analyzer and a condensation particle counter (TSI; model 3786), as described previously (Jayne et al. 2000). The ionization efficiency was found to be 7.0 $\times$ 10$^{-5}$ before experiments and 6.0 $\times$ 10$^{-5}$ after the experiments. The collection efficiency, used to correct for nonunity collection, was calculated as the percentage of organics detected by the AMS compared with the CPC, assuming a density of 1.4 mg/m$^3$, and was found to be ∼70%. The method used to analyze the elemental composition of the aerosol is described in detail elsewhere (Canagaratna et al. 2015).

**ROS measurement.** An online particle-bound ROS instrument (OPROSI; University of Basel) was installed on line D with an 10-fold ejector diluter (Palas) to trace the oxidative potential as described previously by Wragg et al. (2016). The occurrence of ROS is based on H$_2$O$_2$ measurements.

**Offline aerosol measurements.** In parallel to the online chemical and physical characterization, PM$_{2.5}$ particles were sampled on prebaked (500°C) quartz fiber (QF) filters (Pall Corporation; Tissuquartz) for offline chemical characterization. Filters with a total sampling volume of 600 L were collected either at a 10-L/min flow rate (60 min collection time) or at a 5-L/min flow rate (120 min collection time), respectively.

**Particulate carbon and chemical SOA composition.** EC and organic carbon (OC) were determined from the QF filters using a thermal-optical carbon analyzer (Desert Research Institute model 2001A; Atmoslytic Inc.) following the IMPROVE_A protocol (Chow et al. 2007). The SOA composition was investigated with two complementary MS techniques from particles collected on filters as described above: Direct inlet probe–high-resolution time-of-flight mass spectrometer (DIP-HRTOFMS; Pegasus GC-HRT 4D; LECO) (Käfer et al. 2019) and comprehensive two-dimensional gas chromatography (GC $\times$ GC–TOFMS; Pegasus BT 4D GC $\times$ GC; LECO) with thermal desorption (TD). For DIP-HRTOFMS, round filter punches with a diameter of 2 mm were analyzed by TD in the ion source (40°C–2°C $\times$ 400°C) in four replicates. Raw spectra were blank corrected, summed over the whole run, and found ions were assigned to elemental formulas limited to 1–50 carbon, 0–102 hydrogen, and 0–5 oxygen atoms within a relative mass error window of 5 ppm. Last, ions with odd nominal mass, which represent fragments from the electron ionization, were removed from the data set to focus on molecular ions. The TD-GC $\times$ GC–TOFMS was operated with an OPTIC-4 GC inlet system (GL Sciences), with helium (Helium 5.0; Linde AG) as the carrier gas and a GC column set consisting of an SGE BPX5 capillary column [5% phenyl polysilphenylene–siloxane, 60 m,
0.25 mm internal diameter (i.d.), 0.25 μm film thickness (df; SGE) in the first dimension (1D) and an SGE BPX50 capillary column [50% phenyl polysilphenylene–siloxane, 1.5 m, 0.1 mm i.d., 0.1 μm df; SGE] in the second dimension (2D). The desorbed semi-volatile organic compounds (SVOCs) were cryogenically focused via the cryogenic trapping system CryoFocus-4 (GL Sciences) at −100°C using liquid nitrogen. The temperature for TD in the OPTIC-4 inlet system was gradually ramped at 2°C/s from 40°C to 300°C to gently introduce aerosol particle constituents onto the GC column with reduced thermal fragmentation. The inlet purge time was 100 s at a column flow of 1 mL/min and a split flow of 100 mL/min. The desorption flow rate was 2.6 mL/min in splitless mode. After TD, the column flow was adjusted to 1 mL/min, and the split flow to 100 mL/min, for the remainder of the measurement. After 10 min of holding the initial temperature of 40°C in the primary oven, it was ramped to 2°C/min from 40°C to 250°C, after which a gradient of 5°C/min was applied to 330°C and held for 10 min. The secondary oven was offset by +20°C from the primary oven, and the modulator temperature was offset by 15°C to the secondary oven temperature. The modulation period was 5 s, with a hot pulse time of 1.5 s. The MS transfer line temperature was set to 300°C. Mass acquisition was done from 20 to 700 Da at 100 spectra/s. The electron energy was 70 eV, and the ion source temperature was 250°C. Data acquisition and processing was carried out using the ChromaTOF software (version 5.5; LECO). Postprocessing was done with a minimum peak signal-to-noise value (S/N) of 1,000, which resulted in a total peak number of 397 and 798 peaks for SOA_{AP}_{SP} and SOA_{AP}_{NP}_{SP}, respectively. 

Transmission electron microscopy (TEM) images. 

Transmission electron microscopy (TEM) images were taken for selected experiments by guiding a small volume (100 mL/min) of the aerosol flow for 2–10 min through a carbon sampling grid (400 mesh copper; Agar Scientific). Sample grids were stored at room temperature (RT) at low humidity in a desiccator prior to analysis using a TEM (JEM-2100F; JEOL Ltd) at 200 kV.

**ALI Exposure Systems and Cell Culture**

**ALI exposure.** Two custom-made automated exposure systems (Vitrocell Systems) were used to expose cells at ALI at different dilutions of the aerosols [undiluted (1:1), 1:3, 1:10, and 1:30]. The tested aerosol was guided through a size-selective impactor that excluded particles with size fractions >PM10, before entering the ALI exposure system and the main reactor. The ALI exposure systems were operated with different settings compared with previous publications (Mühlhopf et al. 2016; Oeder et al. 2015). The total aerosol flow (inlet) was reduced to 5 L/min owing to the limited aerosol flow through the PAM reactor. The cabinet was heated to a temperature of 39.4°C to reduce water condensation in the tubes. Both systems comprised three Vitrocell 6/6 CF Stainless modules, thus enabling the exposure of six inserts of a 6-well format per module. Every position in the module was supplied with separate air flow over a trumpet taken from the main reactor. Exposure to the tested aerosol was conducted in 12 positions per ALI exposure system, in which the aerosol was passed over the cells growing on Transwell inserts and deposition was controlled only by diffusion. A simplified scheme of the setup is shown in Figure 1. In addition to the aerosol exposures, each system had a separate clean air (CA; purified compressed laboratory air) exposure sector serving as controls (6 positions per ALI exposure system). Incubator control cell cultures were important to assess the impact of the ALI exposure system itself on the cultured cells. The temperature of each module containing the cells was continuously measured and controlled via external water baths, and although the cabinet was heated to 39.4°C, the modules themselves had to be cooled down to 37°C for optimal cell culture environment. Humidified aerosol and CA (85% RH) were operated with a 100–1 mL/min flow rate over every position in the ALI exposure system, as described by Mühlhopf et al. (2016). Every evening the ALI exposure systems were dried using filtered ambient air, and the tubing to and from the modules was also dried by starting a filtered ambient air exposure (~30% RH) with an increased flow rate of 200 mL/min for 20 min. Between different aerosol exposures, the reactors were taken apart and cleaned with 70% ethanol. The impactors were cleaned once a week, as well as before changing the aerosol.

**Estimation of the particle deposition in ALI.** The deposited PM mass per area was calculated using the following equation.

\[
\text{Deposited mass per area \left[ \text{ng/cm}^2 \right] = \frac{\eta \times Q \times N \times t \times \rho_p \times V_p}{A},}
\]

where \( \eta \) is the deposition efficiency; \( Q \) is the aerosol flow; \( N \) is the particle number concentration (particle count per volume); \( t \) is the duration of the exposure; \( \rho_p \) is the particle density; \( V_p \) is the particle volume, assuming spherical particles; and \( A \) is the area of the deposition plate. The size-dependent deposition efficiency of particles (\( \eta \)) in the ALI exposure system is calculated using the theory described by Lucci et al. (2018). In the model, the deposition of particles is generally controlled by size-dependent diffusion and sedimentation mechanisms. Large particles deposit by sedimentation, whereas small particles deposit by diffusion. The particle deposition efficiency is controlled by various parameters (e.g., particle size and density, aerosol flow, temperature, pressure, and geometry of the system). In the present study, the size-dependent particle number concentration was used, which was measured by the SMPS at line D. The mean effective density of each aerosol type was calculated by forcing the mass concentration measured by SMPS to be equal to the mass concentration measured by a TEOM. Particle density influences the calculations in two ways: first, determining the deposition efficiency, and second, and more importantly, by converting the deposited number of particles to deposited mass. Aerosol flow and temperature were 100 mL/min and 37°C, respectively.

**Cell lines and ALI exposure.** A549 human alveolar epithelial cells (ATCC; CCL-185) and EA.hy926 hybrid human endothelial cells (kindly provided by Dr. S. Moertl, Helmholtz Zentrum) were routinely cultured in high-glucose Gibco Dulbecco’s Modified Eagle Medium: Nutrient Mixture F-12 (DMEM/F-12) (ThermoFisher Scientific; 31331-028) supplemented with 5% (vol/vol) fetal bovine serum (FBS) (ThermoFisher Scientific; 10500-064), and 100 U/mL penicillin and 100 μg/mL streptomycin (P/S; Sigma-Aldrich; P4333) in a humidified incubator at 37°C and 5% carbon dioxide (CO₂). For the mono- and coculture exposure experiments, A549 cells were seeded on the same day on transferrable 24-mm Transwell inserts with a polyester membrane (0.4–μm pore-size; type #3450; Corning) 96 h before the exposure experiments at a density of 1.8 × 10⁶ cells/mL per insert (3.8 × 10⁶ cells/cm² growth area) with 1.5 mL of cell culture medium provided at the basal compartment of the Transwell. Forty-eight hours after the initial cell seeding, the culture medium on the apical side for both cell models was removed to generate ALI conditions, and fresh cell culture medium was added in the basal compartment. Twenty-four hours later, the inserts for the coculture were inverted; 1 × 10⁷ EA.hy926 cells per insert (0.21 × 10⁶ cells/cm² growth area) were seeded in 750 μL of medium; and after 1 h, the insert was turned back and fresh medium was added to the basolateral compartment of the Transwell. For the monoculture, the medium was renewed to ensure equal treatment of both cell culture models. On Day 5, the day of the exposure experiments, inserts with mono- and cocultures were placed.
in the exposure modules of the ALI exposure system (Vitrocell Automated Exposure Station Standard Version) with 1.8 mL serum-free DMEM/F12 medium supplemented with 1% P/S and 15 mM N-2-hydroxyethylpiperazine-N-2-ethane sulfonic acid (HEPES) buffer solution (ThermoFisher Scientific; 15630-056) at the basolateral compartment. Cells were then exposed for 4 h to the conditioned (85% RH, 37°C) and differently diluted aerosols [undiluted (1:1), 1:3, 1:10, and 1:30]. All experiments were performed in at least three independent exposures. After the exposure, the effects of the aerosols on the cells were examined with several assays, and the exposure medium was collected on ice for direct analyses or frozen at −80°C for later analyses.

**Immunofluorescence**

To check for a confluent cell monolayer, the membranes were cut out from the Transwell inserts on the day of the exposure and were washed twice in phosphate-buffered saline (PBS), fixed with 4% formaldehyde (Paraformaldehyde; Carl Roth; 4980.1) for 12 min, and washed three times with 0.1% bovine serum albumin (BSA) (Sigma-Aldrich; A8412) in PBS, before staining with Phalloidin A488 (1:100; Sigma-Aldrich; 49409) and 4',6-diamidino-2-phenylindole (DAPI) (1:1,000; Sigma-Aldrich; D9542) in 1% BSA and 0.1% Triton-X in PBS for 1 h at RT. Membranes were washed three times in PBS, once in double-distilled water, and embedded in fluorescence mounting medium (Glycergel; DAKO; Agilent; C056330-2). Slides were observed on a Lionheart FX Automated Microscope and pictures captured for illustration.

**Cell viability assay and live cell microscopy.** To determine cell viability, immediately after the exposure, A549 inserts were transferred to a 6-well plate, washed once with PBS before adding 1 mL prewarmed fresh exposure medium (serum-free DMEM/F12+1% P/S and 15 mM HEPES) with 10% PrestoBlue HS Cell Viability Reagent (ThermoFisher Scientific; A13262) to the apical and basolateral compartments. After an incubation of 45 min at 37°C in the incubator, aliquots of the basal and apical medium were pipetted into a 96-well plate, and the quantification of metabolically active cells was performed by measuring the fluorescence at 570 nm with a spectrophotometer (MULTISKAN SKY Microplate Spectrophotometer; ThermoFisher Scientific). The results are presented as percentage cell viability compared to untreated controls, exposed cells, and positive controls for both untreated controls, exposed cells, and positive controls for both A549 and EA.hy926 cells. A Trypan Blue in an automated cell counter (Luna-II; Logos Biosystems; BioCat). The alkali concentration of the comet assay was performed according to the mini-gel comet assay method previously described (Di Buchianico et al. 2017) to detect DNA single- and double-strand breaks, as well as alkaline labile sites. Cells exposed to 30 μM hydrogen peroxide for 5 min on ice were used as positive controls. On each slide, eight mini-gels were prepared, including untreated controls, exposed cells, and positive controls for both A549 and EA.hy926 cells. At least three independent slides per condition were prepared, and 100 nucleioids per mini-gel were scored using CometScore (version 2.0; TriTek Corp.) on 1:10,000-dilution SYBR Green (ThermoFisher Scientific; S7563) stained slides. A Lionheart FX automated microscope was used to take 20 × magnification micrographs of the stained slides. Data are shown as percentage DNA breaks (% DNA in tail) from at least three independent exposures with two technical replicates.

**IL-8 measurement.** Aliquots of the collected and −80°C stored exposure media were thawed and analyzed in a 96-well plate, using the enzyme-based immunosorbent assay (ELISA; R&D Systems; DY208) for the pro-inflammatory cytokine IL-8, according to manufacturer’s instruction. In brief, a 96-well plate was coated with 100 μL of diluted human IL-8 capture antibody overnight at RT. On the next day, the plate was washed three times with wash buffer [0.05% Tween 20 (Santa Cruz; 9005-64-5) in PBS, pH 7.2–7.4], blocked with 300 μL block buffer (1% BSA, pH 7.2–7.4) for 1 h, after which the washing step was repeated. Thawed samples of the A549 monoculture were diluted 1:2 and samples of the coculture 1:3 in reagent diluent (0.1% BSA and 0.05% Tween 20 dissolved in PBS) and IL-8 standards were prepared (31–2,000 pg/mL). One hundred microliters of either the samples
or the standards were added to the plate for 2 h at RT. After washing three times with wash buffer, the plate was incubated with 100 μL of detection antibody for 2 h at RT. The washing step was repeated, and 100 μL of streptavidin–horseradish peroxidase was added to each well for 20 min. After another washing step, 100 μL of 3,3′,5,5′-tetramethylbenzidine (TMB; Cell Signaling Technologies; 7004P6) was used as an substrate and incubated for 20 min before 50 μL of stop solution (sulfuric acid) was added, and the fluorescence was measured at 450 and 540 nm in a microplate reader (Varioskan Lux multimode microplate reader). Results are presented as IL-8 in picograms per milliliter from at least four independent exposures with one technical replicate.

**Angiogenesis Assay**

EA.hy926 cells were seeded at a density of 100,000 cells per well (2.6 × 10^5 cells/cm² growth area) in a 12-well plate. After 24 h, the attached cells were treated with a 1:1 mixture of fresh medium and conditioned medium (CM) for 24 h. The CM represents the exposure medium that was collected and stored at −80°C after the 4-h exposure to the different undiluted aerosols. After 24 h, the cells were trypsinized and seeded in fresh cell culture medium at 2 × 10^5 cells per well (6.2 × 10^5 cells/cm² growth area) in a 96-well plate precoated with a growth factor-reduced BME Matrigel (Cultrex in vitro angiogenesis assay; R&D Systems; 3470-096-K). Tube formation was captured 24 h after seeding (10 × objective; Lionheart FX Automated Microscope; BioTek). The angiogenic potential, which was measured at 450 and 540 nm in a microplate reader (Varioskan Lux multimode microplate reader). Results are presented as IL-8 in picograms per milliliter from at least four independent exposures with one technical replicate.

Angiogenic score = 

\[
\left( \frac{\text{(No. of sprouting cells)} \times 1 + (\text{No. of connected cells}) \times 2 + (\text{No. of polygons} \times 3)}{\text{Total number of cells}} \right) + (0, 1 \text{ or } 2)
\]

The addition of 0, 1, or 2 to the total value depended on the presence of a complex mesh. No complex mesh is represented by the addition of 0 points; for the existence of luminal structures consisting of two to three cell layers, an addition of 1 point is necessary; and for luminal structures of greater than three cell layers, an additional value of 2 is added. Results are presented as Angiogenic score from at least three independent experiments and two technical replicates.

**Statistical methods.** Each experiment was performed at least in triplicate. The results of three or more independent experiments were expressed as the mean ± standard error of the mean (SEM). Differences between the groups were analyzed using one-way analysis of variance (ANOVA) with the Welch-Satterthwaite approximation for unequal variances (Welch 1947). Multiple comparisons using the Bonferroni correction to control the inflation of type I errors were conducted for all ANOVA results with a p < 0.05 as post hoc analysis for sample comparison. All data were analyzed with R environment (RStudioTeam 2019, http://www.rstudio.com/). Graphs were illustrated using GraphPad Prism for Windows (version 9.0.0; GraphPad Software).

## Results

### Characterization of the SOA Components of the Two Aerosol Types

All online instruments confirmed stable and reproducible aerosol feeds and aging conditions over the entire exposure period of 4 h (Figure S1A–E). Moreover, BC and OC concentrations were similar for both precursors. In addition, strong similarities between both precursors were observed for averages of geometric mean of particle size, equivalent photochemical ages, and OC fractions. An overview of the SOA concentrations and properties, as well as of the bare SPs, is compiled in Table 1. TEM micrographs of both SOAs revealed similar particle shape classes of soot agglomerates coated with organic material, whereas pure SPs seemed to retain their more fractal structures (Figure S2). The particle number of SOANAP-SP was slightly higher compared with SOAPIN-SP (Table 1), and spontaneous nucleation of SOANAP-SP, forming particles with a mobility diameter of <50 nm, occurred to a minor extent (Figure S1F). Consequently, the estimation of the particle mass deposition suggested a 1.5-fold higher deposition of SOANAP-SP (28 ng/cm²) compared with SOAPIN-SP (17 ng/cm²).

To explore how SOAPIN-SP is chemically distinct from SOANAP-SP, we performed untargeted GC × GC-TOFMS analysis for the SVOCs. The chemical composition of the two generated SOAs differed widely in individual molecular composition, compound classes, and oxidation state (Figure 2A–F). In GC × GC with a nonpolar column in the first and a polar column in the second

Figure 2. Chemical characterization of SOANAP-SP and SOA\textsubscript{PIN}-SP. (A, B) GC × GC-TOFMS bubble plots for SOANAP-SP (A) and SOA\textsubscript{PIN}-SP (B) at atmospheric OH age ≈ 3 d. Bubble sizes correspond to their respective peak areas. (C, D) Assignment of representative peaks from GC × GC-TOFMS for SOANAP-SP (C) and for SOA\textsubscript{PIN}-SP (D) to their molecular formulas via comparison with NIST mass spectral library and retention indices (excluding peaks with inconclusive MS spectra). (E, F) Areas of the 100 peaks with the highest signal intensities from GC × GC-TOFMS classified by compound classes and functional groups for SOANAP-SP (E) and for SOA\textsubscript{PIN}-SP (F). The classified 100 compounds account for 77.4% and 60.4% of the total abundance for SOANAP-SP and SOA\textsubscript{PIN}-SP, respectively. Corresponding numerical data for (A–D) are shown in Tables S1 and S2 and for (E, F) in Tables S3 and S4. Note: GC × GC-TOFMS, comprehensive two-dimensional gas chromatography–time-of-flight mass spectrometer; MS, mass spectrometer; NIST, National Institute of Standards and Technology; OH, hydroxyl; SOANAP-SP/SOA\textsubscript{PIN}-SP, soot particles (SP, CAST soot; 1 mg/m\textsuperscript{3}) together with either naphthalene (4 mg/m\textsuperscript{3}) or \textbeta-pinene (4 mg/m\textsuperscript{3}) photochemically aged with OH radicals in a potential aerosol mass reactor.

Retention dimension, compounds were first separated according to their vapor pressures, corresponding to the respective carbon number and boiling point on the x-axis, and by polarity on the y-axis (Figure 2A, B). The compounds were classified into both ring-opening and -retaining aromatics, as well as cyclic and noncyclic compounds, based on their appearance in the 2D chromatogram and mass spectrometric signature (Figure S3). SOANAP-SP was clearly dominated by aromatic structures. Aromatic compounds, retaining the naphthalene carbon backbone of two six-rings, eluted slightly faster in the second dimension compared with the ring-
opening aromatic compounds and, therefore, were located below the ring-opening aromatics in the 2D chromatogram. For SOA_{PIN-SP}, the region between 3,000 and 5,000 s revealed peaks of highest abundance, corresponding to a boiling point range of ∼170°C to 290°C for linear alkanes with a molecular weight of ∼140–230 Da and carbon numbers between C_{10} and C_{16}. For SOA_{NAP-SP}, the region with peaks of highest abundance was between 3,700 and 6,000 s, corresponding to a boiling point range of ∼220°C to 330°C for linear alkanes with a molecular weight of ∼170–270 Da and carbon numbers between C_{12} and C_{19}.

In all aging experiments, we detected more individual compounds for SOA_{PIN-SP} than for SOA_{NAP-SP} within the assessable boiling point range. At a minimum peak S/N of 1,000 the total peak number for SOA_{NAP-SP} and SOA_{PIN-SP} was 397 and 798 peaks, respectively. The top 100 peaks with the highest peak intensities presented in Figure 2A,B,E,F contributed to 77.4% and 60.4% of the total peak intensity for SOA_{NAP-SP} and SOA_{PIN-SP}, respectively (Figure S4, Tables S1 and S2). Furthermore, SOA_{NAP-SP} consisted of fewer, but more abundant, compounds in signal intensity (Figure S4A). Despite performing an elaborated cleaning procedure, carryover effects between experiments could not be fully avoided. However, Figure S4 illustrates that the carryover was limited when considering the chemical profiles and abundances, showing that the investigated two SOA types resulted in entirely different chemical species with respect to the detected molecular structures. For SOA_{PIN-SP}, these compounds were mostly comprised of oxygenated cyclic and acyclic compounds (Figure 2D,F), whereas in SOA_{NAP-SP}, we mostly found aromatic structures (Figure 2C,E).

DIP-HR-TOFMS measurements were performed for the analysis of higher oxidized compounds, exceeding the application range of GC x GC-TOFMS. Complex patterns of nonaromatic (H/C > 1) oxidized fragments (O/C > 0) with up to four oxygen atoms were recognized, although oligomers could not be unambiguously identified (Figure 3E,F). The DIP-HR-TOFMS measurements showed a lower H/C-ratio for SOA_{NAP-SP}, pointing again to its more aromatic structure compared with SOA_{PIN-SP}. The resulting O/C values from the AMS measurements indicated a slightly higher photochemical oxidation of SOA_{NAP-SP} compared with SOA_{PIN-SP} (Figure 3B,D). In addition, SOA_{PIN-SP} appeared well within the triangular space spanned by the relative fractions of m/z 43 vs. m/z 44 (Figure S5).

**Cytotoxic Effects after Exposure to Soot Aerosol Coated with SOAs**

For our study we established two different cell culture models, one using an alveolar epithelial lung (A549) cell line as an ALI monoculture model and another using an A549/human endothelial (EA.hy926) cell line ALI coculture model (Figure 4A, graphical illustration). Immunofluorescence staining confirmed a confluent single cell layer in both cell culture models shortly before the aerosol exposure (Figure 4A, right panel). To explore how SOA_{PIN-SP} and SOA_{NAP-SP} affect the cell culture models, we first performed a resazurin-based viability test on the A549 monoculture. Exposure to the undiluted pure SPs did not significantly decrease cell viability (Table S6). In addition, SOA_{PIN-SP} did not significantly affect cell viability in all tested dilutions (p > 0.05) and exhibited slightly

![Figure 3. Oxidation state of SOA_{NAP-SP} and SOA_{PIN-SP}. (A,C) Occurrence of reactive oxygen species (ROS) in SOA_{NAP-SP} (A) and SOA_{PIN-SP} (C) by measuring H_{2}O_{2} with an online particle-bound ROS instrument (OPROSI) in micromoles per meter cubed of n independent experiments (SOA_{NAP-SP}: n = 2, SOA_{PIN-SP}: n = 3). (B,D) O/C ratios determined by AMS for SOA_{NAP-SP} (B) and SOA_{PIN-SP} (D) of n independent experiments (SOA_{NAP-SP}: n = 10, SOA_{PIN-SP}: n = 11). (A–D) The upper and lower hinges of the box plots represent the first and third quartiles (the 25th and 75th percentiles) of the distribution. Figure 4. Cell viability and LDH release after 4-h exposure to SOANAP-SP and SOAPIN-SP. (A) Schematic overview of the cell seeding procedure of mono- and coculture, as well as representative immunofluorescence images of mono- (A549; upper image) and coculture (A549/EA.hy926; lower image) on the day of aerosol exposure, stained for actin filaments (phalloidin, green) and nuclear stain (DAPI, blue). Scale bar: 200 μm. (B) Cell viability of A549 monoculture after the exposure to SOAPIN-SP and SOANAP-SP measured by resazurin-based assay. Results are presented as the mean cell viability compared with the incubator ctrl ± SEM of n independent experiments (SOAPIN-SP: n = 4, SOANAP-SP: n = 5 for all dilutions and CA ctrl: n = 8) and dotted lines denote the regression line for the respective SOA forced through the CA ctrl. (C) Propidium iodide staining (PI, red) of A549 monoculture after 4 h exposure with SOAPIN-SP and SOANAP-SP for all dilutions, as well as a CA ctrl. Hoechst nuclear stain (blue). Scale bar: 1,000 μm. Shown are representative images of at least three independent experiments. (D) LDH release (mU/mL) of A549 monoculture after the exposure to SOAPIN-SP and SOANAP-SP. (E) Comparison of LDH release (mU/mL) of the mono- and coculture after the exposure to SOAPIN-SP (left panel) and SOANAP-SP (right panel). (B,D,E) Results are presented as absolute values ± SEM of n independent experiments (SOAPIN-SP: n = 4, SOANAP-SP: n = 5 for all dilutions, and CA ctrl: n = 9) and dotted lines denote the regression line for the respective cell culture models and SOA forced through the CA ctrl. (B,D,E) Aerosol exposure groups were compared by performing a one-way ANOVA and statistical significance was calculated with multiple comparisons for the dilutions within one aerosol exposure group using the Bonferroni correction. p-Values are presented in the graph and in the tables below the graphs. Corresponding numerical data for (B,D,E) are shown in Tables S6 and S7. Note: ANOVA, analysis of variance; CA, clean air; ctrl, control; DAPI, 4′,6-diamidino-2-phenylindole; inc, incubator; LDH, lactate dehydrogenase; OH, hydroxyl; SEM, standard error of the mean; SOA, secondary organic aerosol; SOANAP-SP/SOAPIN-SP, soot particles (SP, CAST soot; 1 mg/m³) together with either naphthalene (4 mg/m³) or β-pinene (4 mg/m³) photochemically aged with OH radicals in a potential aerosol mass reactor.
lower viability (78%) following undiluted aerosol exposures [half-maximal inhibitory concentration (IC50) > 1:1 dilution; Figure 4B]. In contrast, cells exposed to SOANAP-SP had lower cell viability in the range from 70% cell viability for the 1:30 diluted aerosol to the significant ($p < 0.0001$) 40% for the undiluted aerosol (IC50 = 1:1.5; Figure 4B) compared with control cells. The undiluted SOANAP-SP aerosol cell exposures showed significantly lower viability than undiluted SOAPIN-SP treatments ($p = 0.0008$). This significant difference was also confirmed by normalizing to the deposition that is needed to achieve the respective IC50 values of SOAPIN-SP and SOANAP-SP. By liner regression analysis, the normalized mass deposition for SOANAP-SP ($R^2 = 0.6$, $p = 0.0005$) resulted in an IC50 value of 18 ng/cm², whereas the IC50 value for SOAPIN-SP (SOAPIN-SP: $R^2 = 0.7$, $p = 0.001$) did not even reach its highest concentration. No linear regression could be calculated for the exposure with SP ($R^2 = 0.01$) because of the similar results in all dilutions. No significant difference in cell viability was observed for the CA controls compared with the incubator controls (100% cell viability). The resazurin-based assay was not conducted with the coculture model owing to space limitations in the ALI exposure system. The results from the cell viability assay of the monoculture were also corroborated by live cell microscopy, where we saw a higher number of dead cells after the exposure to SOANAP-SP than to SOAPIN-SP, and only a slightly higher number of dead cells in the CA control compared with the incubator controls (Figure 4C).

The difference in cell viability prompted a further elucidation of how the tested biogenic and combustion-derived SOAs affected the used cell cultures. In the monoculture, a concentration-dependent ($R^2 = 0.5$, $p = 0.03$) difference in LDH level (higher in exposed cells vs. control) was detected following exposure with SOAPIN-SP, with the highest effect at dilution 1:1 (undiluted). Compared with SOAPIN-SP, the exposure to SOANAP-SP in the monoculture led to the release of higher LDH concentrations in all dilutions with ∼200 mU/mL in dilutions 1:30, 1:10, and 1:3 and 330 mU/mL in dilution 1:1 (undiluted) (Figure 4D). These aerosol-specific effects on LDH release in the monoculture were confirmed by the results observed with the coculture system, in which we monitored the same trends with a lower magnitude, but with no statistically significant effect compared with the monoculture (Figure 4E). Model systems exposed to CA were not significantly different from each other in LDH release (33 mU/mL for monoculture; 38 mU/mL for coculture).

**Effects on Oxidative Stress and Genotoxicity by Soot Aerosol Coated with SOAs**

Next, we investigated why SOANAP-SP induced a higher cytotoxic effect compared with SOAPIN-SP. No organic or inorganic peroxides were present in the undiluted pure soot aerosol (Table 1), 3.6 μmol/m³ hydrogen peroxide (H2O2)-equivalent in the undiluted SOAPIN-SP and 14.1 μmol/m³ H2O2-equivalent in the undiluted SOANAP-SP, indicating a higher oxidative potential of SOANAP-SP with respect to SOAPIN-SP (Figure 3A,C). These results were corroborated through analysis of MDA, a marker for cellular oxidative stress. Both in the monoculture (Figure 5A) and the coculture (Figure 5B), exposure to SOANAP-SP induced the highest release of MDA in all dilutions (concentration-dependent; $R^2 = 0.98$, $p = 0.0002$) with a peak at the undiluted (1:1) aerosol (45 ng/mL). The exposure with SOAPIN-SP resulted in a concentration-dependent ($R^2 = 0.8$, $p = 0.15$) higher release of MDA, with the greatest release of 23.3 ng/mL (monoculture) and 18 ng/mL (coculture) at dilution 1:1 (undiluted) (Figure 5A,B). Also here, the cells exposed to undiluted pure soot had only a slightly higher release of MDA in the monoculture (12 ng/mL; SP column in Table S6) and in the coculture (11 ng/mL; SP column in Table S7). These findings of elevated oxidative stress markers after SOA exposure motivated the genotoxicity investigation, given that oxidative stress can cause DNA damage. Interestingly, the exposure with SOAPIN-SP and SOANAP-SP resulted in a flatter response compared with the MDA results for the dilutions from 1:10 until 1:1 (undiluted) for SOAPIN-SP (9–11% DNA breaks) and from 1:30 until 1:1 (undiluted) for SOANAP-SP (13–16% DNA breaks) in A549 cells in both cell culture models (Figure 5C,D). Remarkably, after the exposure to SOANAP-SP, we detected a significantly higher percentage of DNA breaks in EA.hy926 cells that were not directly exposed to the aerosols [7% DNA breaks (1:3), $p = 0.02$ to 1:10 dilution; 8% DNA breaks (1:10), $p = 0.03$ to 1:10 dilution], suggesting possible secondary genotoxic effects. Because of space limitations in the ALI exposure system, the baseline of DNA breaks were defined from the incubator control, showing 4% of DNA breaks. Moreover, the exposure to undiluted SP resulted in 8% DNA breaks of A549 cells in both cell culture models and 4% for EA. hy926 cells (SP column in Tables S6 and S7).

**Impacts on Inflammatory Response and Angiogenesis by Soot Aerosols Coated with SOAs**

The exposure to SOAPIN-SP resulted in a non-concentration-dependent response with IL-8 concentrations between 335 pg/mL and 382 pg/mL in the monoculture. SOANAP-SP, however, induced a higher concentration-dependent ($R^2 = 0.92$, $p = 0.002$) IL-8 release with 600 pg/mL at the undiluted (1:1) aerosol (Figure 6A). The CA control was at 341 pg/mL and the exposure to undiluted SP showed no further difference in IL-8 release (360 pg/mL; SP column in Table S6). Contrary to the results regarding cytotoxicity and oxidative stress, SOA exposures of the coculture resulted in a significantly higher IL-8 release compared with the monoculture in both aerosols and all dilutions (Figure 6B). Exposure of the coculture to SP had no significant effect on IL-8 release (520 pg/mL; SP column in Table S7). Moreover, we wanted to elucidate how the greater secretion of inflammatory cytokines may directly regulate the functional cross-talk between A549 and EA.hy926 endothelial cells. By treating EA. hy926 cells with conditioned media from the A549 exposure to the different aerosols, we found that only media from the SOANAP-SP exposure induced a higher angiogenic potential of EA.hy926 (Figure 6C,D). We saw the same effect with the conditioned medium from the coculture exposed to SOANAP-SP, where we found a significant difference compared with the CA control and even SOAPIN-SP (Figure 6C,D). No angiogenic effect of the conditioned media collected after the exposure to SP from both cell culture models was observed (Tables S6 and S7).

**Discussion**

The present study provides new insights into the impact of SOA of anthropogenic and biogenic volatile organic precursors in the presence of soot core particles in airway ALI model systems at the cellular and molecular levels. It was observed that the formation of an SOA layer by adsorption and condensation on freshly emitted SP could cause a substantial aggravation of toxic effects, differing from combustion-only SP, which caused only slight toxic effects. Thus, it could be expected that the toxicity of primary particulate emissions in the ambient air during a medium strong atmospheric aging (e.g., equivalent to a range of a few days) was enhanced. Here, SOAs formed from a biogenic (β-pinene) or a combustion-related organic precursor component (naphthalene) were investigated and compared. We showed that an in-depth physicochemical aerosol characterization delivered relevant information for inhalation toxicology studies and that the different chemical identity of tested aerosols may explain the different toxicological outcomes. Cells exposed to SOANAP-SP—here as surrogate for atmospherically processed
combustion emissions—exhibited lower cell viability, higher oxidative stress, and genotoxicity and induced inflammatory and angiogenic responses compared with those exposed to SOA$_{PIN-SP}$. In addition, concentration-dependent biological effects were observed following exposures to SOA$_{PIN-SP}$ and SOA$_{NAP-SP}$ in several assays. Moreover, the different toxicological responses in the used mono- and coculture systems pointed out the importance of using multicellular in vitro models to improve the understanding of possible cellular crosstalk.

**Chemical Distinct Characteristics of SOAs Responsible for Cellular Effects**

Chemical and physical transformation of VOCs in the atmosphere lead to the formation of amorphous solid or semi-solid SOA particles (Dennis-Smith et al. 2014); however, investigations of the in vitro toxicity of primary combustion emissions (i.e., of SPs) photochemically aged in the presence of SOAs are scarce. The photochemical aging of both naphthalene and $\beta$-pinene in the presence of soot aerosols resulted in SPs coated with SOA materials that simulated aged atmospheric SPs. These aerosols had similar physicochemical characteristics in terms of mass, size distribution, particle number, particle geometric mean diameter, and atmospheric OH radical age, as well as EC and OC content. This is of great importance because it remains unclear whether SOAs with similar physical characteristics also cause similar biological effects (Burkholder et al. 2017; Künzi et al. 2015; National Academies of Sciences, Engineering, and Medicine 2016). The present study shows that SOA$_{NAP-SP}$ compared with SOA$_{PIN-SP}$ had an adverse outcome on cell viability, oxidative stress, genotoxicity, and inflammatory and angiogenic responses.
et al. 2018, 2019; Han et al. 2020) and, in addition, induced a pro-
angiogenic potential in endothelial cells. This also holds true if we
account for the calculated mass-specific deposition, which was
greater for SOANAP-SP. Even though this study con-
cluded that for aerosols with a comparable parti-
cle size distribution the di-

Figure 6. Inflammatory and angiogenic response triggered by SOANAP-SP and SOA\textsubscript{PIN}-SP. (A) IL-8 release (pg/mL) in A549 monoculture after the exposure to SOA\textsubscript{PIN}-SP and SOANAP-SP. (B) Comparison of IL-8 release (pg/mL) of the mono- and coculture after the exposure to SOA\textsubscript{PIN}-SP (left panel) and SOANAP-SP (right panel); (A,B) Results are presented as absolute values ± SEM of \(n\) independent experiments (SOA\textsubscript{PIN}-SP: \(n = 4\), SOANAP-SP: \(n = 5\) for all dilutions and CA ctrl: \(n = 12\)) and dotted lines denote the regression line for the respective cell culture models and SOA forced through the CA ctrl. Aerosol ex-
posure groups were compared by performing a one-way ANOVA and statistical significance was calculated with multiple comparisons for the dilutions within one aerosol exposure group using the Bonferroni correction. \(p\)-Values are presented in the graph and in the tables below the graphs. (C,D) EA.hy926 cells were cultured for 24 h in media collected after the exposure to SOA\textsubscript{PIN}-SP and SOANAP-SP, as well as, CA control and then allowed to from tube structures on Matrigel for 24 h. Shown are representative images of EA.hy926 tubes from the indicated treatments (C) and quanti-
fication (D) of three independent experi-
ments. Scale bar: 1,000 \(\mu\)m. Corresponding numerical data for (A–D) are shown in Tables S6 and S7. Note: ANOVA, analysis of variance; CA, clean air; CM, conditioned medium; ctrl, control; IL-8, interleukin-8; OH, hydroxyl; SEM, standard error of the mean; SOA, secondary organic aerosol; SOA\textsubscript{PIN}-SP/SOANAP-SP, soot particles (SP, CAST soot; 1 mg/m\(^3\)) together with either naphthalene (4 mg/m\(^3\)) or \(\beta\)-pinene (4 mg/m\(^3\)) photochemically aged with OH radicals in a potential aerosol mass reactor.

and inflammation consistent with previous studies (Chowdhury et al. 2018, 2019; Han et al. 2020) and, in addition, induced a pro-
angiogenic potential in endothelial cells. This also holds true if we
account for the calculated mass-specific cellular deposition, which was
greater for SOANAP-SP. Even though this study confirmed the health risks of specific SOA compounds and pointed out the benef-
its of \textit{in vitro} exposures in an ALI exposure system, it has its limi-
tations. The applicability of ALI exposures to human exposures remains uncertain as long as it is di-

The chemical characterization revealed distinct qualitative differences in the chemical composition of SOA\textsubscript{PIN}-SP and SOANAP-SP, which is potentially responsible for the observed differences in the cellular toxicity. Thereby, the chemical compo-
sition of the derived SOA depended very much on the chemical functionality of the precursor and the low organic content of the
SP seed. The detected chemical structures corresponded to typi-
cal first-generation degradation products of the respective precur-
sor. For SOA\textsubscript{PIN}-SP, the major first-generation degradation product was nopinone in the particulate and acetone in the gas
phase (Hohaus et al. 2015; Kaminski et al. 2017). In SOANAP-SP, we mostly found aromatic structures, which are well-known aging products originating from ring-opening and -retaining reactions of the aromatic precursors (Chan 2009). The photochemical degradation of naphthalene started with the addition of a OH rad-

cal, forming a hydroxyhexadienyl-type radical. From an intra-
molecular rearrangement, the first-generation product naphthol
was formed. If the hydroxyhexadienyl-type radical reacts with oxygen, ring-opening structures may be formed, such as 2-form-
methylcinnamaldehyde (Keyte et al. 2013). 1-Naphthol and 2-naph-
thol, which were generated in significant yields, may be further oxidized by other oxidants, such as hydroperoxides, and oxygen
to naphthoquinones (Keyte et al. 2013). Upon further oxidation, early generation products increase in oxygen-containing moieties and could polymerize under the applied conditions (Kenseth et al. 2018; Sato et al. 2016).

Moreover, differences in volatility of the formed compounds from β-pinene and naphthalene aging could be derived from the GC×GC signatures, generally indicating more volatile compounds for SOA\textsubscript{PIN-SP}. In SOA\textsubscript{NAP-SP}, the aromatic structure was usually maintained and dominated the SOA composition, for which toxic effects on human health are well documented and include carcinogenic and mutagenic effects, as well as reproductive defects (Drwal et al. 2019; Gaspari et al. 2003; Perera et al. 2002).

Concerning elemental aerosol particle composition, the O/C value for SOA\textsubscript{NAP-SP} (0.77) exceeded that of SOA\textsubscript{PIN-SP} (0.61), agreeing with a previous study about the photooxidation of naphthalene and α-pinene (Chowdhury 2018). In addition, the average carbon oxidation state (O\textsubscript{C}), which is calculated as $2 \times O/C - H/C$ was higher for SOA\textsubscript{NAP-SP} (0.5) than for SOA\textsubscript{PIN-SP} (−0.43). SOA\textsubscript{NAP-SP}, with 0.3 to 0.7, showed a similar range of O\textsubscript{C} as reported in the literature for emissions from residential logwood combustion (Hartikainen et al. 2020) and gasoline direct injection vehicles (Pieber et al. 2018) of the same photochemical age (~3 equivalent days). The O\textsubscript{C} increases upon oxidation owing to the formation of carbon–oxygen bonds and/or the breaking of carbon–hydrogen bonds through, for example, functionalization or fragmentation reactions (Kroll et al. 2011). In this context, the oxidative addition of polar functional groups to the carbon backbone could be observed for both aerosol types.

We found that SOA\textsubscript{PIN-SP} appeared well within the triangular space spanned by the relative fractions of $m/z$ 43 vs. $m/z$ 44, representing ambient organic aerosols from global AMS field studies (Ng et al. 2011), thus supporting its use as a surrogate for atmospherically processed combustion emissions. The difference in O/C between SOA\textsubscript{NAP-SP} and SOA\textsubscript{PIN-SP} might be a consequence of the slightly higher photochemical age of the SOA\textsubscript{NAP-SP} or differences in formation pathways, including the release of secondary VOCs from fragmentation. In contrast to the data from AMS measurements, for which correction procedures were developed to improve the accuracy of the derived elemental ratios (Canagaratna et al. 2015), in the data evaluation from the DIP measurement the peak at $m/z$ 43,989 of CO$_2$, which increases from, for example, thermal decarboxylation of carboxylic acids in the SOAs, is not considered because of a too high peak intensity from background air and the associated high uncertainty of the result. Consequently, the result of higher O/C for SOA\textsubscript{PIN-SP} than for SOA\textsubscript{NAP-SP} could indicate a higher abundance of carboxylic groups in SOA\textsubscript{NAP-SP}, represented by the AMS, but not by DIP, measurements. Future studies beyond the scope of this manuscript will discuss data from AMS and DIP in more detail.

It is possible that the aerosol’s toxicity largely depends on the degree of oxidation induced by atmospheric aging. Thus, the hazards of functional groups of the detected organic compounds could have a decisive impact. Studies on PAHs, such as naphthalene, have demonstrated specific toxic effects on cells (IARC 2010), and these effects may be enhanced by their oxidized derivatives (Chowdhury et al. 2018). However, it has to be noted that this increased toxicity reflected specific oxidation stages and could change with oxidation mechanism given that studies have also shown a declined toxicity during aging for naphthalene (Han et al. 2020) or hydrocarbons (Jiang and Jang 2018). For selected terpenes emitted from coniferous plants, including also β-pinene, no adverse cytotoxic or genotoxic effects in A549 human lung cells were found in an ALI exposure study by Gminski et al. (2010), although mutagenic and carcinogenic effects were described for specific compounds such as α, β-unsaturated aldehydes and 2-octen (Gminski et al. 2010). In our study, there were similarities between the abundance of most functional groups and related compound classes in SOA\textsubscript{PIN-SP} and SOA\textsubscript{NAP-SP}, such as furans, aldehydes, and ketones. The oxidation of naphthalene may lead to first-generation open-ring dicarbonyl products and closed-ring epoxide products (Wang et al. 2007). A recent *in vitro* proteome-wide study by Han et al. (2020) pointed out the importance of short-lived unsaturated carboxyls in aged naphthalene as the main toxic components at the posttranslational level. Furthermore, the oxidation of furan-containing compounds favored the formation of epoxides, which are associated with enhanced harmful cellular effects (Peterson 2013; Tabaran et al. 2019). The intracellular oxidation of aldehyde groups by enzymes of the aldehyde dehydrogenase family has been associated with adverse effects on various cell types, especially concerning tumor initiation, metastasis, and therapeutic resistance (Ma and Allan 2011; Rebollido-Rios et al. 2020; Rodriguez-Torres and Allan 2016). Photooxidation of β-pinene resulted in nopinone as a major first-generation product, which in a second step may form nine-carbon multifunctional compounds (Sato et al. 2016). In contrast to aldehydes, ketones are less reactive and less electrophilic, characteristics that can be associated with lower toxicological effects. However, minor changes in the molecular structure could be decisive for adverse outcomes (LoPachin and Gavin 2014; Schwöbel et al. 2011). Future studies are warranted to evaluate the particle cellular uptake of the tested aerosols to better understand the bioaccessibility of specific chemical compositions and their cellular effects.

Our results indicate that the differential toxicity of the precursors [half maximal oral lethal dose (LD$_{50}$) (rat) naphthalene: 2,000 mg/m$^3$ (U.S. EPA 2021b); oral LD$_{50}$ (rat) β-pinene: 5,000 mg/m$^3$ (U.S. EPA 2021a)] was retained after an equivalent photochemical age of 3 d. However, depending on particle size, altitude, and atmospheric compartment, the lifetime of a particle spans a range from a few hours up to 2 wk (Raes et al. 2000; Williams et al. 2002). From a chemical perspective, atmospheric aging increased the O/C ratio of any organic aerosol constituent toward the limit of 2 determined by CO$_2$, steadily increasing their functionalization (Kroll et al. 2011); yet AMS analysis of organic aerosol from the Northern Hemisphere did not exceed O/C ratios of 1.2 (Ng et al. 2010), also not for highly oxidized molecules (Ehn et al. 2014). Moreover, atmospheric aging involves several processes and conditions, such as distinct differences during day- and nighttime or ambient levels and distributions of nitrogen oxides (NO$_x$) species, triggering different reaction pathways. There is particularly strong evidence that exposure to nitrogen dioxide is associated with adverse effects on human health (Atkinson et al. 2018; Mills et al. 2015) and leads to the formation of atmospheric mutagens from PAHs (Atkinson and Arey 1994). However, the general role of NO$_x$ in atmospheric aging on the toxicity of SOA is in the early stage of research (Chowdhury et al. 2019). Hence, it remains an unanswered question if, when, and how different structural properties of SOA precursors are influencing the chemical and toxicological properties of the respective SOA during photochemical aging.

### The Importance of Using Mono- and Coculture Systems in Aerosol Studies

Although monocultures provide information on direct toxicological effects of nanomaterials, recent studies have pointed out that multicellular culture systems are important tools for modeling an *in vivo* physiological cellular environment, including the...
interaction between different cell lines (Bengalli et al. 2013; Klein et al. 2013; Lacroix et al. 2018). It is well known that, apart from pulmonary adverse health effects, PM$_{2.5}$ can also induce an increased risk for cardiovascular morbidity and mortality (Brook et al. 2010). Dysfunction of endothelial cells in particular is suspected to play a major role in inducing cardiovascular injury after the inhalation of PM$_{2.5}$ in a cohort of healthy individuals (Pope et al. 2016), which highlights the importance of the used epithelial–endothelial coculture in our study to depict possible underlying mechanisms.

In our epithelial monoculture, SOA$_{\text{NAP}}$-SP induced a 10-fold higher, and SOA$_{\text{PIN}}$-SP a 7-fold higher, release of LDH in the undiluted aerosol compared with CA controls. Interestingly, the relative difference in LDH was lower in our epithelial–endothelial coculture (5-fold) than in the monoculture after the exposure to both undiluted aerosols. It is conceivable that this effect was the result of an enhanced physical barrier due to the addition of endothelial cells on the basolateral side of the membrane. Notably, the diffusion of particle-related H$_2$O$_2$ content is presumed to represent a main pathway for inducing intracellular ROS formation (Liu et al. 2020). It was already shown that the SOA oxidative potential depends on the hydrocarbon precursor identity, with biogenic SOA having a lower water-soluble oxidative potential than anthropogenic SOA (Tuet et al. 2017). Indeed, we found a greater peroxide content in SOA$_{\text{NAP}}$-SP (∼3.5 times higher compared with SOA$_{\text{PIN}}$-SP) and a higher abundance of MDA (∼2 times higher compared with SOA$_{\text{PIN}}$-SP in the undiluted aerosol), which is an end product of the lipid peroxidation induced by free radicals (Ayala et al. 2014), in the cell culture medium of both mono- and cocultures. Assuming an enhanced physical barrier in the coculture system, but observing no differences in MDA release in the mono- and cocultures after the exposure to the tested SOAs, suggested an additional release of MDA from endothelial cells, possibly induced by oxidized phospholipids and cytotoxic compounds of the epithelial cells (Landar et al. 2006). Epidemiological and in vivo studies with PM$_{2.5}$ have identified inflammatory responses as a major adverse outcome pathway (Yan et al. 2016), and in vitro studies have highlighted the impact of endothelial cells in secreting pro-inflammatory mediators (Karki and Birukov 2020). In line with our observations of SOA$_{\text{NAP}}$-SP inducing cellular cytotoxicity and oxidative stress, we observed a greater release of IL-8 in the monoculture after the exposure to SOA$_{\text{NAP}}$-SP (∼2-fold higher in the undiluted aerosol) compared with SOA$_{\text{PIN}}$-SP (no difference in the undiluted aerosol). In addition, we showed higher secretion of IL-8 in the coculture compared with the monoculture system (∼2-fold higher after the exposure to undiluted SOA$_{\text{PIN}}$-SP and SOA$_{\text{NAP}}$-SP). Inflammation and oxidative stress are main drivers for the induction of DNA strand breaks (Möller et al. 2014). Consistent with our previous shown results on MDA and IL-8 release, we observed DNA breaks of ∼10% for undiluted SOA$_{\text{PIN}}$-SP and ∼16% for undiluted SOA$_{\text{NAP}}$-SP in the monoculture. Moreover, experiments with conditioned media-based techniques revealed secondary genotoxic effects of nanomaterials (Akerlund et al. 2019; Evans et al. 2019). To the best of our knowledge, this is the first study that showed secondary genotoxic effects on cells in a coculture system at ALI where a cell–cell interplay was provided. Here, we observed genotoxic effects on endothelial cells (8 % DNA breaks) after the exposure with SOA$_{\text{NAP}}$-SP [undiluted (1:1) and 1:3 diluted] but not after SOA$_{\text{PIN}}$-SP exposures. Further studies should investigate this observation to exclude a possible translocation of PM through the insert membrane and thus a direct effect on endothelial cells (Wang et al. 2019). However, the enhanced release of IL-8 in the coculture cell model compared with the monoculture following SOA$_{\text{NAP}}$-SP exposure, supported our assumption of secondary genotoxic effects given that cytokines may promote genomic instability and IL-8 is a pro-angiogenic factor, potentially explaining the observed cross-activation of endothelial cells (Aivaliotis et al. 2012; Heidemann et al. 2003). Furthermore, the angiogenesis assay with a conditioned media-based approach affirmed the cross-activation of endothelial cells after the exposure to SOA$_{\text{NAP}}$-SP. No difference in the angiogenic potential between the conditioned media of the mono- and cocultures was observed, indicating that besides IL-8 other pro-angiogenic factors and oxidative stress may also play a decisive role (Kim and Byzova 2014). The conditioned media of the coculture exposed to SOA$_{\text{PIN}}$-SP induced a decreased angiogenic potential, whereas in the conditioned media of the monoculture, no difference from the control was detected. Future studies beyond the scope of this manuscript should investigate how SOA$_{\text{PIN}}$-SP differently altered the angiogenic potential of endothelial cells in our experimental setup. In general, dysfunction of endothelial cells is associated with adverse health outcomes. Although a reduced angiogenic potential of endothelial cells after the inhalation of PM$_{2.5}$ has been observed in previous studies (Lan et al. 2020), and can be an indication for a compromised ventilation–perfusion ratio of the lung, an enhanced angiogenic potential is one of the hallmarks for several interstitial lung diseases (Ackermann et al. 2020).

Nonetheless, although coculture models are enhancing in vitro studies by including the interaction between cell types, to what extent this may reflect an in vivo physiological cellular environment is always of concern and further optimization and standardization are needed. For instance, although our coculture model focused on the deposition of inhaled PM$_{2.5}$ on epithelial cells, it is well accepted that resident immune cells are also directly targeted upon inhalation and thus, including immune competent cells would be an improvement of the model. Moreover, A549 cells at ALI are known to partially mimic the property of an alveolar epithelium (Wu et al. 2017a), but drawbacks include their low expression of tight junctions or adherence proteins and their inability to form a fully differentiated and polarized epithelium (Papazian et al. 2016). Therefore, the additional usage of different epithelial cells, which could represent a heterogeneous population of several different epithelial cell types, would have benefited our study. However, owing to the complexity of our experimental setup, we found with A549 a robust cell line that is suitable for large and repetitive studies. Further studies comparing simultaneous performed aerosol exposures in vivo with different in vitro cell culture systems should help to extrapolate within the framework of replacement, reduction, and refinement.

Conclusions

The ubiquitous layer of SOA components that condenses onto primary particles can have a strong impact on PM toxicity. In particular, SOA-coated combustion SPs showed higher toxicity compared with fresh combustion SPs. This emphasizes the importance of atmospheric transformations for the toxicity and adverse health effects of ambient aerosol particles and may help to explain the high numbers of air-pollution related mortality and morbidity cases identified by epidemiological studies. This study also demonstrated that different SOA precursors led to different toxicological outcomes at comparable exposure conditions. A typical anthropogenic, aromatic SOA precursor (naphthalene) mixed with SPs, led to condensation of higher oxidized, aromatic SOAs of higher oxidative potential on the SPs and induced stronger toxic effects in the investigated lung cell models. In contrast, a typical biogenic, aliphatic SOA precursor (β-pinene) led to condensation of less oxidized, aliphatic SOAs of lower oxidative potential on the SPs and induced milder toxic effects in the
investigated lung cell models. Our findings highlight the role of different structural–chemical properties of photochemically aged SOAs for *in vitro* toxicological outcomes. Moreover, we emphasize the importance of multicellular culture systems to model a normal physiological cell environment with intercellular cross-talk. Future studies will also focus on an in-depth characterization of the used aerosols and of aerosol-specific effects on transcriptomic and proteomic outcomes.
